- Use of fuller’s earth cat litter in California was challenged because of the presence of crystalline silica. It was necessary to obtain a “Safe Use Determination” by the Sorptive Minerals Institute to enable the sale of most types of cat litter in the state.
- The National Institute for Occupational Safety and Health (NIOSH) conducted a health study to ensure that the type of elongate crystals in palygorskite in the Florida–Georgia fuller’s earth district did not constitute an asbestiform mineral health hazard.

PRODUCT PACKAGING, TRANSPORT, AND MARKETING

Finished granular fuller’s earth products such as cat litter, oil absorbents, and floor-sweep compounds are sold in consumer-attractive paper or plastic packages of 5 to 50 lb or in metric sizes for export markets. Cat litter packaging has evolved from unweighed filling of semicalcined clay into hand-stapled bags in 1952 to fully automated bag-filling units that shrink-wrap bundles which are then conveyed onto automatically stretch-wrapped pallets for warehousing and then loading onto trucks or railcars.

Agricultural chemical carriers, jet fuel filtration products, bleaching clay granules, anticaking or dry-flow agent clay powders, specialized drilling muds, and gelling or thickening agents are shipped in 40- or 50-lb paper bags, polypropylene bulk big-bags, bulk truckloads, or railcars.

Some export fuller’s earth products are shipped overseas in large metal shipping containers, covered barges, or bulk ship holds. Although the industry packaging trend is toward nearly complete automation, some fuller’s earth products continue to be hand-bagged and -palletized.

Finished fuller’s earth products may be distributed to a market radius of only a few hundred miles for typical high-density, low-absorption cat litter or to worldwide markets for high-grade bleaching clays. Order size can range from barge load or shipping cargo bays, or 80- to 120-truck load special promotions, to individual pickup truck loads destined for the local hardware store. Generally, the main tonnage of fuller’s earth products is shipped to market in truckloads, railcars, or in metal shipping containers.

Individual fuller’s earth customers can be hardware stores, municipal or hazardous waste landfills, city or university athletic fields for turf enhancement granules, jet fuel purification facilities at major airports, or multibillion-dollar distributors for chemical, grocery, or discount consumer sales outlets.

Product sales go through regional or national distributors or directly to the wholesale or retail customer. Fuller’s earth products are sold in the neighborhood grocery store in attractive small packages for household cat litter or to a paint manufacturer for use as a thickener and antidrip agent.

The overall trend in the fuller’s earth industry is to develop new products that better satisfy the particular customer’s needs and allow a higher added-value price over standard or commodity grades. New product development research must consider fuller’s earth mineralogy, physical and chemical specifications, existing patent rights, customer service and packaging preferences, and extra processing and energy cost requirements before launching innovative higher-value products.

The future of the U.S. fuller’s earth industry depends on developing and patenting new special-use products and reaching new types of market applications.

Kaolin

Robert J. Pruet and Sam M. Pickering, Jr.

INTRODUCTION

Kaolin is a global industrial mineral primarily used as (1) a pigment to improve the appearance and functionality of paper and paint, (2) a functional filler for rubber and plastic, (3) a ceramic raw material, and (4) a component for refractory, brick, and fiberglass products. Other lower-volume uses for kaolin include chemical manufacture, civil engineering, agricultural applications, and some pharmaceuticals. The limited availability of suitable raw material, extremely competitive market conditions, and the technological complexity of kaolin processing and kaolin product functionality creates a high barrier of entry in to kaolin production. Rock and soil containing kaolin minerals occur over wide areas on most continents, but large high-purity kaolin deposits that are capable of supplying large processing facilities and are accessible to global transportation infrastructures are rare. Therefore, the majority of the world's kaolin is mined from sedimentary kaolin deposits located in the United States and Brazil and from primary kaolin deposits in the United Kingdom and Germany. The large size of operations in these regions is driven in part by demand in the paper market for large volumes of consistent quality pigment and by the need to cover the large fixed cost base that is required to mine and process kaolin ore into marketable product.

Definitions

Kaolin is a white or nearly white clay comprising naturally occurring kaolin group minerals. It is distinguished from other industrial clays containing high levels of kaolin minerals—such as ball clay and fire clay—by its whiteness, fine particle size, and kaolin group mineral content (Table 1). The white color of kaolin can occur natu-

rally or result from extensive processing to remove color-bearing minerals and organic compounds that adsorb certain wavelengths of visible light. A second component of kaolin's white appearance is derived from its fine particle size, which causes light to scatter. In most commercial products, kaolin contains particles with an equivalent spherical diameter that is generally finer than 2 μm , though some grades of kaolin products contain particles about 10 μm in size. The term *hydrous kaolin* generally refers to processed kaolin product that contains kaolin minerals with their structural water or hydroxide component. *Calcined kaolin* refers to the thermally processed kaolin exposed to temperatures higher than 450°C to form metakaolin, or to temperatures higher than 1,000°C to form high temperature minerals such as mullite, spinel, and cristobalite.

Crude kaolin ore deposits are contained in a variety of kaolinitic rock types. *Primary kaolin* generally describes a kaolin ore altered from an igneous or metamorphic rock that was kaolinized in situ by hydrothermal or weathering processes. Varieties of primary kaolin are China-clay rock and residual kaolin. Saprolite can be residual kaolin that forms from the weathering of felsic igneous and metamorphic rocks. *Sedimentary kaolin* is a kaolin ore formed through sedimentary depositional processes. *Secondary kaolin* is sedimentary kaolin comprising transported mineral particles. Though the term sedimentary kaolin was originally synonymous with secondary kaolin, it is clear that many kaolin ores deposited as sediments have undergone some postdepositional kaolinization of other minerals or recrystallization of kaolin minerals (Pruett 1993; Hurst and Pickering 1997). The primary or sedimentary origin of a kaolin deposit influences the exploration, mining, and processing methods used to manufacture a kaolin product (Figure 1). A variety

Table 1. Features that distinguish kaolin from ball clay and fireclay

	Kaolin	Ball Clay	Fireclay
Occurrence	Altered rock, sedimentary rock	Sedimentary rock	Sedimentary rock
Processing	Unprocessed, air-float, water-washed, delaminated, calcined	Unprocessed, air-float, some slurry	Unprocessed, calcined
Properties	White or nearly white, clay particle size	Highly plastic clay, contains some organic matter and/or swelling clay	Low in alkalis, calcium, and iron; high alumina and silica; does not deform at high temperature
Use	Pigment, filler, ceramic, refractory	Ceramic, refractory	Refractory
Synonyms	China clay, paper clay, white clay, <i>bolus alba</i>	Pipe clay	Firestone, pot clay, refractory clay, sagger

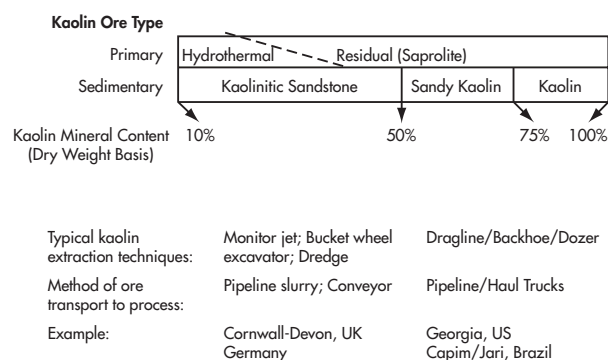

Figure 1. Relationship between kaolin mineral content and extraction method for kaolin ore types

of terms (Table 2) are used to describe rock types that contain kaolin minerals in sufficient concentration to be used or considered as kaolin ores or are associated with kaolinized rock units.

GEOLOGY

Mineralogy

Kaolin minerals are dioctahedral 1:1 phyllosilicates having a sheet of silicon atoms in tetrahedral coordination with four oxygen atoms and a sheet of aluminum atoms in octahedral coordination with two oxygen atoms and four hydroxide molecules (Figure 2). The basal oxygen atoms of the tetrahedral sheet form a crystal face, and the apical oxygen in the silica sheet are shared with aluminum. The remaining two thirds of oxygen in the octahedral sheet are shared with hydrogen (i.e., hydroxides) and form the opposing crystal face. Hydrogen bonding between the basal oxygen of the tetrahedral (T) sheet and hydrogen of the octahedral (O) sheet in an adjacent layer define a cleavage plane that enables delamination of kaolinite into flat platy particles. The difference between kaolinite, dickite, and nacrite is related to differences in the stacking order of unit layers. Kaolinite has a single tetrahedral-octahedral (TO) layer; dickite has a two TO-stacking unit layer with higher structural order than kaolinite; and nacrite has a six TO-stacking unit layer and ordered distribution of octahedral vacancies forming a crystal with rhombohedral symmetry. Halloysite has two layers of water between each TO layer in its hydrated form. Hydrated halloysite is also referred to as 10Å-halloysite, indianite, and endellite. Dehydrated halloysite is called 7Å-halloysite or metahalloysite.

Kaolinite is the most common kaolin mineral and has the greatest industrial importance. The kaolinite crystal lattice shows a range of defect concentrations and isomorphous substitution of iron for aluminum in the octahedral sheet and perhaps aluminum for silicon in the tetrahedral sheet (Schroeder and Pruett 1996). The terminology to describe kaolinite defects is confusing and discordant. Kaolinite crystal defects were initially described as well-crystallized or poorly crystallized, terms used by Grim (1953), which changed in the scientific literature to well-ordered or poorly ordered, and evolved to high-defect or low-defect, which is currently favored by mineralogists publishing in academic journals such as *Clays & Clay Minerals*. In the patent literature, industrial mineralogists and technologists typically use the terms well-crystallized or poorly crystallized, as originally used by Grim.

The Hinckley index is a method recognized by industry for measuring the relative levels of defects in kaolinite powders. The Hinckley index of kaolin is calculated using x-ray powder diffraction patterns (Figure 3). High-defect kaolinite has broad x-ray peaks,

a low Hinckley index (<0.6), and is called poorly ordered or poorly crystallized kaolinite. Low-defect kaolin has sharp x-ray diffraction peaks, a high Hinckley index (>0.7), and is called well-ordered or well-crystallized kaolinite. Hinckley index relates generally to the physical properties of kaolin, particularly to particle size. Kaolin with a high Hinckley index is typically coarse particle size (<70 wt % <2 µm), whereas kaolin with a low Hinckley index is typically fine particle size (>80 wt % <2 µm).

The accessory mineral content of kaolin is a result of its geological origin and the separation processes used for beneficiation. Primary kaolin ore from different deposits or even the same deposit generally show a wide variation in mineralogy that is controlled by the degree of alteration by weathering and hydrothermal processes. Primary kaolin contains significant amounts of nonkaolin minerals that are resistant to alteration. Common minerals that resist alteration processes are quartz, muscovite, tourmaline, and zircon. The margins of primary kaolin deposits can have sharp boundaries or can gradually change into less-altered rock that shows only partial feldspar and mica alteration. Rock that is partly kaolinized can have some host minerals from the parent rock, such as feldspar or biotite, or some minerals that are first series products of chemical alteration, such as halloysite, illite, vermiculite, or smectite.

Sedimentary kaolin typically does not contain high concentrations of unstable or labile minerals from the parent source rock (Figure 4), and the content of minerals such as quartz and mica in commercial deposits is low because coarse sand- and silt-sized particles were separated from clay during sediment transport. The fine silt- or clay-sized fractions that make up the bulk of sedimentary kaolin deposits contain impurities such as anatase, illite, smectite, hydroxyl-interlayer vermiculite, and mixed-layered clay minerals. Sedimentary kaolin that is associated with oxidized sediments contains iron oxide and iron hydroxide minerals that are common in soil environments such as hematite and goethite. Sedimentary kaolin that is associated with reducing anoxic depositional environments will generally contain organic matter and may contain iron sulfides such as pyrite, marcasite, or both.

Clay-sized titania minerals such as anatase are common in sedimentary kaolin and are uncommon in primary kaolin. Anatase and its precursor pseudorutile are weathering products of ilmenite and titanium-bearing biotite mica inherited from the parent rock (Schroeder, Pruett, and Melear 2004). The chemistry of anatase appears to reflect its precursor minerals (ilmenite, micas) by having minor levels of iron and trace levels of chromium, zirconium, and niobium substituting for titanium, thus causing the mineral to have a brown to tan color which detracts from the whiteness of kaolin products. Leucogene originating from ilmenite typically occurs as coarse aggregates that can be removed by standard gravity separation or magnetic separation processes, whereas anatase resulting from biotite mica alteration is typically finely disseminated in the kaolin ore and responds well to flotation or selective flocculation for removal.

OCCURRENCE

Kaolinite is a very widespread mineral across the earth's surface, especially as a major component of soils in humid subtropical and tropical areas. Kaolin deposits (Ross and Kerr 1931; Patterson and Murray 1984) of sufficient purity, brightness, whiteness, and suitable mineral-water slurry viscosity, however, are rather rare.

In general, kaolin deposits can occur as the following:

- Sedimentary bodies with fairly to extremely low "grit" content in various stages of oxidation and recrystallization
- Residual weathering blankets or funnel-shaped hydrothermal alteration zones along fracture patterns from much older aluminous rocks such as granites

Table 2. Kaolin rock terms and definitions

Terms Generic to Kaolin	
Kaolin	A rock mass containing principally kaolinitic clays that are low in iron, and usually white or nearly white in color (Ross and Kerr 1931)
Tonstein	Kaolin composed of volcanic ash that was partly or fully altered to kaolin minerals and is commonly associated with coal deposits.
Terms Typically Related to Primary Kaolin	
China stone	Partly kaolinized granite that is harder than China-clay rock
China-clay rock	Granite showing the highest degree of kaolinization where all feldspar has altered to kaolinite and can readily be broken apart by hand
Cornish stone	China stone
Lithomarge	A smooth indurated variety of kaolin containing a mixture of kaolinite and halloysite
Saprolite	Weathered igneous or metamorphic rock showing primary relict texture that can have a high kaolin mineral content
Terms Typically Related to Sedimentary Kaolin	
Ball clay	Highly plastic secondary clay containing kaolinite and used for ceramics
Fireclay	A clay, typically containing kaolin minerals, with a high silica and alumina content; used as a refractory because it will not deform at high temperature
Flint clay	Kaolin that is smooth, tough, flintlike, and breaks with a pronounced conchoidal fracture
Hard kaolin	A term original used for kaolin used to fill hard rubber that originates from fine-particle-size kaolin deposits located in the Georgia–South Carolina kaolin district. Hard kaolin also occurs in northeastern Brazil. It has a low Hinckley index and tends to break with some difficulty in a rough irregular fracture.
High-alumina kaolin	Kaolin containing minor amounts of hydrous alumina minerals such as gibbsite, boehmite, or diaspore
Kaolinitic sandstone	Sandstone containing significant and potentially separable amounts of kaolin minerals. The sand-sized particle content is >50% by volume or mass.
Sandy kaolin	Kaolinitic sediments generally containing between 5 and 50 wt % sand-sized particles
Soft kaolin	A term originally used for kaolin used to fill soft rubber that originates from coarse-particle-size kaolin deposits located in the Georgia–South Carolina kaolin district. Soft kaolin has a high Hinckley index, tends to be massive, and breaks with a smooth conchoidal fracture.
Underclay	A clay that underlies a coal bed representing a soil from the coal swamp flora. Underclay is commonly kaolinitic and can be a source of ball clay or fireclay.

Figure 4. Sequence of mineral changes from a granite that are associated with (1) weathering, (2) transport and deposition, (3) early stage of postdepositional alteration, and (4) late stage postdepositional alteration for kaolin in central, middle, and eastern Georgia, United States

Modifications from the USGS numbers including the following:
* German kaolin production taken from *Minerals Yearbook 2002*.
† Assumed 15% beneficiated, dry product recovered from crude kaolin.
‡ Includes ball clay.
§ Modified to reflect adjusted volumes for CIS, Czech Republic, and South Korea; and deletion of volume from Columbia.

Figure 5. World production, kt (as compiled by the U.S. Geological Survey [USGS], 2002)

- Weathering alteration deposits of feldspar-rich (arkosic) sedimentary rock

The most prominent world kaolin mining districts are in the United States (southeastern), Brazil (northern), the United Kingdom (Cornwall–Devon), and Germany (Bavaria and Saxony). The volume of beneficiated kaolin produced from these four districts is shown in Figure 5. Kaolin production from some other countries is reported using different metrics such as crude tons mined (Commonwealth of Independent States [CIS], Czech Republic, and the Republic of Korea), or includes ball clay (Australia) or common clays (Colombia). The prominence of U.S., Brazilian, U. K., and German kaolin production is both in terms of volume and quality of beneficiated product that reaches global pigment and filler markets as opposed to local commodity markets where kaolin is sold as inexpensive mineral filler or as a structural component in brick.

United States

In the southeastern United States, kaolin has been mined since colonial times in the upper Coastal Plain areas of Georgia and South Carolina. These deposits are composed of deltaic sediments of Late Cretaceous to Early Tertiary age that represent the Oconee Group (Figure 6).

The major sedimentary units here are cross-bedded, fining-upward coarse- to fine-grained quartz sands which originated as outwash from weathered Paleozoic to Precambrian granitic rock bodies contained in the Piedmont and Blue Ridge provinces of the Appalachian Mountains. Lens-shaped clay accumulations were formed by sediments deposited in low, swampy areas on the advancing delta

Section (thickness not proportional)	Age	Group	Formation	Member	Description of Stratigraphic Units, Including Their Role in Groundwater Oxidation–Recrystallization of Kaolins
	Late Eocene	Jackson or Barnwell	Twiggs Clay	No formal stratigraphic term yet applied.	Smectite fuller's earth, denies recharging oxidizing groundwater access to kaolin beneath unless breached by erosion.
			Clinchfield Sand	Treadwell and Riggins Mill	Fine-grained sand with occasionally abundant marine vertebrate fossils (shark and other fish teeth and bones, etc.).
	Early–Middle Eocene	Oconee	Huber	Jeffersonville*	Fining-upward aquifer sand sequences capped by hard, only partially altered, finer-particle-size, higher-iron kaolin lenses.
	Late Paleocene			Marion*	Soft gray to black unoxidized kaolin and lignite lenses in clayey sands, few to no commercial-quality kaolin deposits.
	Latest Cretaceous		Buffalo Creek*	Not Yet Subdivided	Many fining-upward aquifer sand sequences, capped by soft coarse kaolin lenses that are currently the most heavily mined.
	Late Cretaceous	No formal stratigraphic term yet applied.	Pio Nono	No formal stratigraphic term yet applied.	Arkosic clayey sand with no kaolin lenses, contains no known commercial kaolin deposits. Coarse gravel at base.
	Paleozoic and Pre-Cretaceous	No formal stratigraphic term yet applied.	Piedmont "Basement"	No formal stratigraphic term yet applied.	Metamorphic–igneous complex; weathered granites, gneisses, and phyllites. These crystalline rocks were sources for commercial kaolins.

LEGEND: fk = Finer particle size hard kaolin (both unoxidized and oxidized).
ck = Coarser particle size soft kaolin (both unoxidized and oxidized).
kl = Gray kaolins and lignites.
— U — = Profound unconformity.
- - - U - - - = Subtle unconformity.

*Stratigraphic unit that produces important tonnages of commercial grade kaolins.

Figure 7. Electron photomicrograph showing the fracture surface of coarse kaolin crude that is representative of Cretaceous kaolin deposits in Georgia

Courtesy of IMERYS.

Figure 8. Electron photomicrograph showing the fracture surface of fine kaolin crude that is representative of fine Tertiary kaolin deposits in Georgia

Table 3. Comparison of typical sedimentary characteristics for soft, coarse-particle-size kaolin deposits with those for hard, finer-particle-size kaolin deposits

Typical Characteristics of Sedimentary Kaolins	Soft Kaolin	Hard Kaolin
Texture of crude clay fracture surfaces	Breaks easily into smooth, conchoidal surfaces	Tough, breaks less easily, rough, earthy, hackly surfaces
Larger trace fossils	Burrows and trace fossils very scarce to absent	Common, mainly intertidal trace fossil burrows
Microscopic fossil types of dominant plant pollen and spores	Mainly pollen of upland, back-deltaic, and continental aspect	Trace bacteria, more marine pollen, dinoflagellates, and hystrichospherids
Typical deagglomerated crude clay particle size	Coarser than about 65% to 70% finer than 2 μm	Finer than about 80% to 90% finer than 2 μm
Clay particle crystal habit or morphology	Coarse books, stacks, and vermiforms in a matrix of euhedral thin crystallites, more recrystallized	Vermiforms, books, and stacks very rare or absent, only thin submicron single crystal plates, less recrystallized
Crystallite particle packing relationship	Open, porous, interlocking face to edge packing	Tight, little pore space, face to face packing
Crystal cleavage, ability to produce delaminated products	Coarse vermiforms and books cleave and delaminate well for high aspect ratio products	Hardly delaminates at all, crystal plates are too fine and thin
X-ray diffraction patterns	Well-resolved peaks in the 020, 110, 111, 021, and 021 bands, low crystal defect kaolinite	Poorly resolved peaks in the 020, 110, 111, 021, and 021 bands; diffuse pattern; high crystal defect kaolinite
Hinckley index	High Hinckley index, two phase mixture	Low Hinckley index, single phase
Clay chemistry after deagglomeration removal of detrital minerals	Fe and Ti low, increase with decreasing crude particle size, lower alkali metals	Fe and Ti higher, often same, or increase with decreasing crude particle size, slightly higher alkalis
Accessory detrital mineral suites	Altered muscovite abundant, detrital heavy minerals more mature but less abundant	Muscovite scarce, coarser anatase more abundant, immature heavy minerals
Moist crude clay bulk density and specific gravity	1.2–1.3 st/yard ³ , specific gravity 1.3–1.6	1.3–1.4 st/cu yd, specific gravity 1.6–1.7
Aqueous slurry viscosity at highest-solids concentration	Generally Hercules higher and Brookfield lower	Generally Hercules lower and Brookfield higher
Georgia, geological age, and stratigraphic occurrence	Older, in Georgia in Cretaceous Buffalo Creek Formation or early Paleocene Marion Member	Younger, in Georgia from Early to Middle Eocene Jeffersonville Member of the Huber Formation
Northern Brazil occurrence	Rio Capim District, Para State	Rio Jari District, Amapa State
Depositional environment	Fluvial upland back-deltaic, mostly fresh water	Coastal, marginal marine, often brackish or saline

Adapted from Pickering and Hurst 1989.

front and also in the less saline back-delta areas. These lens-shaped clay units were deposited during several worldwide episodes of marine transgression and highstand along the fall line in Georgia and South Carolina. This process of deposition and the role of weathering and bacterial alteration are more thoroughly described in Elzea Kogel et al. (2000) and Elzea Kogel et al. (2002). Domkowski (1992) suggested that the older Cretaceous coarse kaolin (Figure 7) was derived from weathered granitic and gneissic source

rocks, and the Early Tertiary fine-particle-size kaolin (Figure 8) from phyllic meta-volcanic source rocks. In general, Table 3 describes soft and hard kaolin and holds true for kaolins in both Georgia and the eastern Amazon region of Brazil.

Because the river deltas were heavily overgrown with thick plant cover, the clays were laid down with a considerable organic content of decaying vegetation. The resulting clay deposits were originally rather dark organic, pyritic mud, and usually cap distinct,

Table 4. Comparison of the typical weathering alteration characteristics of reduced and oxidized types of sedimentary kaolins from Georgia

Typical Characteristics of Sedimentary Kaolins	Reduced, Unoxidized Kaolins, Protected from Recharging Fresh Groundwater	Oxidized Kaolins, Well Exposed to Recharging Fresh Groundwater
Moist clay color or shade	Pale gray to brownish gray	Pale pink to cream
Main impurity materials	Dark organic matter, pyrite	Hematite, anatase, and goethite
Stratigraphic and geomorphic occurrence	Typically down-dip, beneath a thick cover of impermeable overburden	Generally up-dip areas, where thick overlying impermeable overburden was eroded away
Amount and type of organic matter	More abundant, readily oxidized	Less abundant
Valence state of iron minerals	Fe ²⁺ , ferrous	Fe ³⁺ , ferric
Extent of recrystallization	Can be lower Hinckley index	Can be higher Hinckley index
Types of industrial processing required to produce well-whitened paper coating clay products	Ozone oxidation or thermal calcination to remove dark organic matter; can be unresponsive to reduced-acid leaching and magnetic separation	Ozone oxidation for removal of dark organic matter not needed, responds well to reduced acid leaching and magnetic separation

Adapted from Pickering, Hurst, and Elzea 1997.

fining-upward, cross-bedded sand depositional sequences. Subsequent weathering oxidation and microbial alteration naturally beneficiated these dark detrital clays to their present near-white purity and appearance (Table 4), perhaps accompanied by extensive in-situ recrystallization of the coarser particle-size Cretaceous kaolin. The table applies to either the soft, coarse, and older clays, as well as the hard, fine, and younger clays. Both the Rio Capim and Rio Jari sedimentary kaolins of the eastern Amazon region of Brazil fit into the well-oxidized side of the table.

In recent years, an attempt has been made to open a primary kaolin district in the Georgia Piedmont near Sparta, Georgia. This venture is developing some exceptionally white and bright high-grit residual kaolin, which has formed as a weathering blanket over the extensive mid-Paleozoic Sparta granite batholith. Feldspars in the Sparta granite have been altered in situ, first to halloysite, which then is transformed to very coarse kaolinite. Because the kaolinite particles were not exposed to the effects of erosion, river transport, and sedimentary deposition, the clay is relatively pure after extensive de-gritting. Potential advantages of this new venture include very high brightness and whiteness, very coarse particle size, and favorable mining conditions with easily excavated low overburden. The main disadvantage of the Sparta primary kaolin is the much higher content of quartz and mica particles.

Smaller volumes of kaolin are mined in several other states in the United States. In the high alumina-clay district near Andersonville, Georgia, and Eufula, Alabama, mixed kaolin and gibbsitic bauxite are mined to produce refractory brick, castings, bodies, and grogs. In the Central Valley of California, refractory-grade kaolin is mined from cross-bedded kaolinitic sands of the Eocene Ione Formation (Bates 1945). The Ione kaolin is a relatively minor by-product of industrial and construction quartz sand production. Somewhat similar kaolinitic sand deposits of the Late Paleocene age Wilcox Formation are mined near Kosse, Texas, where the kaolin is calcined to produce a rather white pigment material. Near Edgar, Florida, similar kaolinitic sands of the Miocene Fort Preston Formation are mined for a popular kaolin product used by art and hobby potters.

Brazil

The fastest-growing kaolin-producing district worldwide is in the eastern Amazon region of northern Brazil (Figure 9). Here sedimentary kaolin is found in coarse deposits along the Capim River south of the Amazon and in very fine particle-size deposits on the east side of the Jari River north of the Amazon (Pickering and Linkous 1997; Pickering 1994). The coarse particle-size kaolin units in the Capim River area occur in the Late Cretaceous age Ipixuna Formation and

are found in grabens located along the southeastern margin of the Cameta Sub-basin (Rossetti and Santos 2003). Rossetti and Santos also propose a lower Tertiary age for the Barreiras Formation, which is the unit containing kaolin along the Jari River. Thus it appears that the eastern Amazon region sedimentary kaolins of Brazil were deposited during the same global sea level highstands that enabled deposition of the Georgia kaolin.

The Jari kaolin deposits were first developed by Ludwig in 1976. The Jari deposit is now mined and processed by Caulim da Amazônia, S.A. (Cadam) to manufacture an ultra-fine glossing pigment for paper coating. Since that time, Cadam's Felipe mine has grown steadily to become what is probably the largest single kaolin mine worldwide in terms of kaolin product volume. This kaolin deposit is unusual in that the main stratum is nearly 35 m thick with very little overburden. The kaolin particle size is very fine, with low grit content, enabling a very high recovery from crude clay. The mine east of the Rio Jari is connected to the processing plant at Munguba, on the west side of the river, by a pipeline beneath the river. The Rio Jari is deep and wide enough at Munguba to permit large ocean-going ships to berth directly at the plant site and load directly with kaolin for worldwide export.

South of the Amazon River are two rapidly growing kaolin operations located west of the Rio Capim. Barges can navigate the Rio Capim, but this river is too shallow for the ocean-going ships that transport kaolin. Both of the Capim producers, Rio Capim Caulim, S.A. (RCC) and Pará Pigmentos S.A. (PPSA), have built the longest kaolin slurry transport pipelines in the world (each >150 km) from their mining areas to the processing plant (RCC) and dryers (RCC and PPSA) near Barcarena, west of Belém. Each drying facility is connected by conveyor to mooring platforms in the river where ships can be loaded with either dry or slurry kaolin products for worldwide export or for domestic use in southern Brazil.

Some advantages of the Brazilian deposits are the following:

- Superior kaolin ores of low grit, very pure kaolin of high brightness and whiteness, with favorable viscosity and paper-coating characteristics
- Access to deep water ship transport to worldwide customers
- Low overburden ratios and relatively simple mining conditions
- Abundant supplies of process water
- Relatively low labor rates
- Major nearby hydroelectric power supply, in the case of the Capim area

For these reasons and others, in recent years the Brazilian kaolin industry has grown rapidly while the other main world producers have experienced considerably less growth (Figure 10).

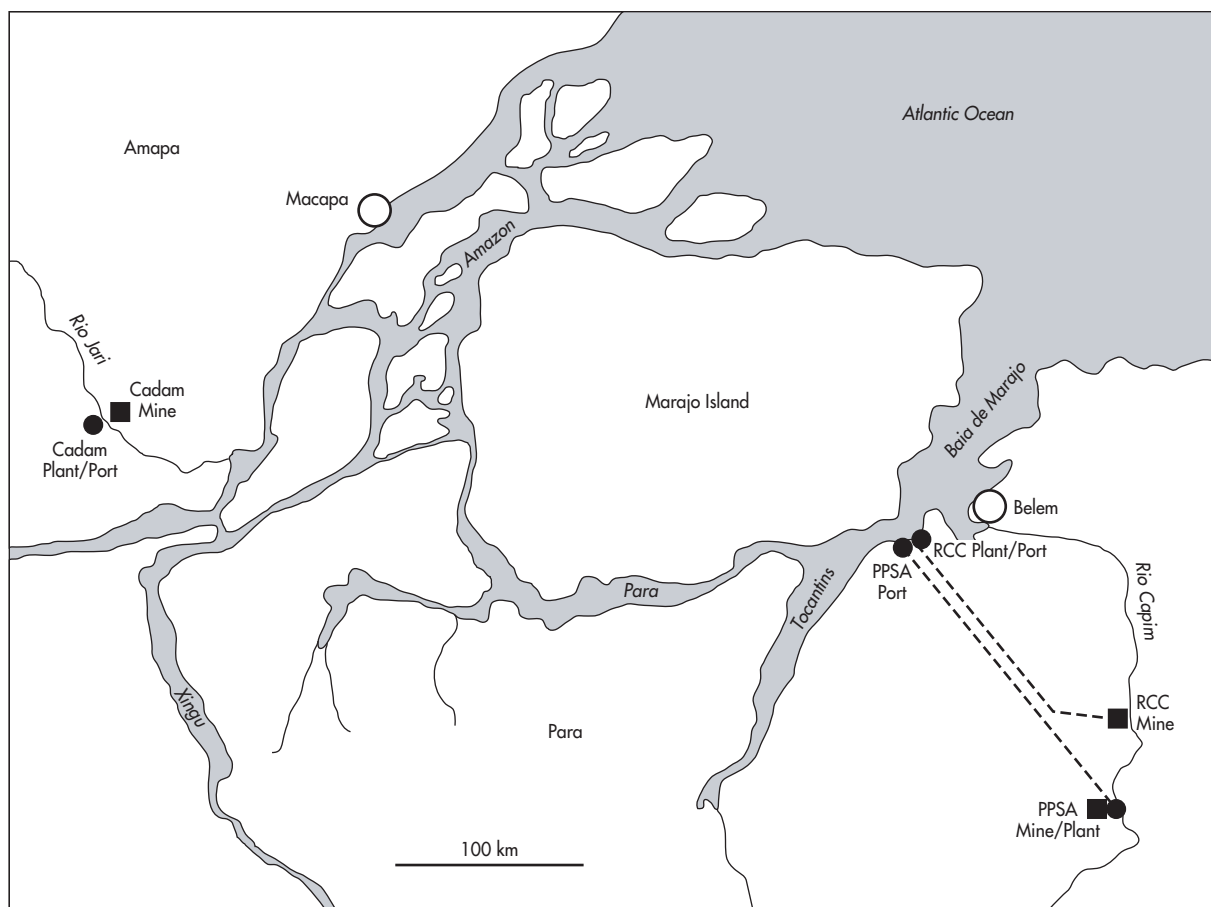

Figure 9. Location of sedimentary kaolin mines with associated pipelines, wet process plants, and ports in northern Brazil near the mouth of the Amazon River

United Kingdom

Primary kaolin has been mined for centuries from hydrothermal alteration deposits in the southwestern United Kingdom, in Cornwall and Devon. Production is from altered fracture zones in the Variscan age Cornubian granite near St. Austell and Tregonning. The kaolin is quite coarse in crystal size, and recovery rates are 8% to 20% because of the very high content of coarse grit. Accessory minerals include quartz, unaltered feldspar, muscovite and biotite mica, tourmaline, topaz, apatite, fluorite, zircon, cassiterite, wolframite, rutile, hematite, and turquoise. The hydrothermal kaolinizing fluids have followed joints, fractures, and faults in the parent granite, often along north-south and northwest-southeast orientations.

The result is roughly funnel-shaped kaolinized deposits dipping steeply and tapering downward to depths as great as several hundreds of meters. As would be expected, the most extensive kaolin deposits were found in areas where major fracture zones intersect or overlap (Exley 1959, 1976; Bristow 1977). Alteration fluids were apparently meteoric in origin, recharging the groundwater system, which has set up slow convection cells carrying the low-temperature hydrothermal fluids (Durrance et al. 1982; Fehn 1985). Bristow (1993) has proposed that the heat source to drive the groundwater convection cells was from radioactive decay from uraninite, apatite, zircon, monazite, and xenotime associated with the granite.

Kaolin in Cornwall-Devon is typically mined using a monitor directed at kaolinized zones along the rock fracture systems. The

Figure 10. Kaolin production from Brazil, the United Kingdom, and the United States, 1900–2002

resulting kaolin slurry drains to the lowest portion of the pits, from which it is pumped up to the degritting equipment. Refined by hydroseparators and cyclones, the degrittied kaolin slurry is pumped to the processing plants to produce kaolin products for the paper filling and coating, paint, adhesives and sealants, rubber, tiles, plastics, and ceramics industries (Manning 1995).

Germany

Sedimentary kaolin is mined from Tertiary age feldspathic-kaolinitic sandstone in the Hirschau and Schnaitenbach areas of Bavaria, in southwest Germany. The sediments were derived from granitic source rocks in the Naab Basin Mountains and are preserved in an east-west trending half-graben. The deposit averages about 76% quartz, 12% feldspar, and 12% kaolin. The quartz has an average grain size of 1 mm, the feldspar about 0.1 mm, and the kaolin about 2 μ m; economic separation depends upon efficient size fractionation.

Overburden is removed and raw ore mined by bucket-wheel excavator and transported by conveyor belt to the adjacent production plant. The ore is mixed with water and dispersant chemical by chain stirrers in stone-lined vats. The sand is removed by screening, and the slurry is refined to remove fine quartz and feldspar. Kaolin recovery is 12% to 16% by weight from the raw ore. The feldspar and quartz sand concentrates are cleaned and sold to local glass industries. The kaolin concentrate is further processed, and the product is used for applications such as paper filler and coater; paint, plastic, rubber filler, and pigment; and ceramics.

In northwest Saxony in southeastern Germany, between Dresden and Leipzig, primary kaolin derived from the alteration of volcanic ignimbrites and porphyritic andesites of the Bohemian Massif are extensively mined. These kaolins are used as pigments in paper, paint, and plastic; as filler in rubber; and as raw material in fine art ceramics and porcelains. Kaolin altered from pitchstone, felsite, and quartz porphyry has been mined at Seilitz, near Meissen, continuously since 1764 (Murray 1989).

INDUSTRIAL PROPERTIES

Chemical Properties

Theoretically, kaolin contains just alumina, silica, and structurally bonded hydroxides (Table 5). However, natural processes form kaolin minerals and cause some iron substitution for aluminum in proportion to iron content of the bulk rock. Low concentrations of mineral impurities not removed by mineral processing will increase the content of the element oxides associated with those impurities. K_2O and MgO levels are typically elevated in proportion to mica content. MgO , CaO , and silica levels are typically elevated in proportion to smectite content. TiO_2 content is proportional to anatase and rutile content. Iron content is influenced by a wide assortment of iron-bearing minerals or iron-substituted kaolinite. Where a high degree of alteration has occurred, alumina and loss on ignition (LOI) at 1,050°C are elevated if gibbsite or boehmite occur in the ore. Commercial specifications related to the chemistry of kaolin products are standard when kaolin is used in ceramic, fiberglass, and refractory applications. The lower concentration of alkaline elements and higher concentration of alumina in kaolin make the material more refractory.

Hydrous kaolin is hydrophilic and can be dispersed at high solids (~70%) in water-based systems, making it an excellent pigment mineral for paper coatings and water-based paints. The aluminum-oxygen and silicon-oxygen bonds in the kaolin mineral layers form a chemically inert particle that is resistant to chemical attack through a wide pH range. This chemical resistance enables kaolin to be used as a filler pigment for acid, Kraft, and alkaline

paper. The absence of an interlayer charge gives kaolinite a very low cation exchange capacity, which is important when high electrical resistance is desired in a material, such as for wire and cable insulators. The kaolinite edge and face surfaces have a net electrostatic charge that is pH dependent (Conley 1996). The octahedral edge of the kaolinite particle has a positive charge below a pH of about 4.5 and becomes negative at a pH of about 11 or higher (Figure 11). The tetrahedral edge of the kaolinite particle becomes more negative at a pH of about 7 or higher. Therefore, kaolin-water systems typically flocculate at a pH of about 6 and lower and are dispersed at a pH of about 6 or higher in the presence of dispersing chemicals (Figure 12). Dispersion is further discussed under Feed Preparation in the Processing section.

Physical Properties

Pure kaolinite is soft and white, has a naturally fine particle size and platy shape, and can be dispersed in water into a fluid slurry with >70% solids. These physical properties make it an excellent white pigment for applications such as paint and paper coatings where whiteness, gloss, and coverage are important. Commercial specifications for the physical properties of kaolin products are standard where kaolin is used as a pigment or functional filler. Each market application has its own specific set of properties measured and reported on the kaolin product certificate of analysis (COA). In general, kaolin physical properties cited on a COA for pigment and filling applications fall into four categories: color, particle size, viscosity of a clay-water slurry, and abrasiveness.

Color

How color and whiteness are reported depends on the market application specific to a geographic region. Brightness is a measure of light reflectance relative to a specific white standard at a specific wavelength. In North America brightness is measured using *Test Method 534, Brightness of Clay and Other Mineral Pigments (d/0° diffuse)* from the Technical Association of Pulp and Paper Industry (TAPPI) and is reported in GE units. GE brightness is reported relative to an MgO standard at 457 nm and is measured using a technical brightness tester. Kaolin pigments with brightness ranging from 84 GE to 88 GE units are considered standard brightness grades; >89 GE units are considered high brightness grades. In Europe, brightness is measured using ISO Standard 2470, *Paper, Board, and Pulp—Measurement of Diffuse Blue Reflectance Factor (ISO Brightness)*, and is reported to pigment consumers in ISO units. The Hunter *L-a-b* color system is used to report pigment reflectance and

shade. L is a measure of reflectance on a scale from zero (none) to 100 (total); a measures redness (positive) or greenness (negative); and b measures yellowness (positive) or blueness (negative). Absence of color is indicated by a zero value in the a and b scales. Several standards also report whiteness and yellowness as a function of light absorption across the visible light spectrum.

Particle Geometry

Particle-size specifications relate to the overall distribution of particle size and to maximum concentrations of coarse particles. Kaolin used for paper applications has particle size measured by a gravitational settling technique such as the SediGraph (Micromeritics Instrument Corporation, Norcross, Georgia). Particle size measured by gravitational settling reports an equivalent spherical diameter that matches well with cut point targets on centrifuges. Particle size may be reported as a mass percent below $2 \mu m$; for example, a No. 1 coating clay will typically have 90 wt % of particles $< 2 \mu m$. Other markets may specify the products in terms of median diameter (d_{50}) and maximum top size. The particle size distribution can be expressed as a particle size at two or more points in a range of particle sizes or can be expressed as a steepness or sorting coefficient that describes the narrowness of a particle-size distribution. A kaolin pigment particle-size distribution can be engineered to

yield $0.3 \mu m$ pores in a paper coating, a pore size optimal for scattering light and higher opacity.

Maximum top size is the largest particle diameter measured by a specified particle-size instrument, which could be a gravitation-settling or laser light-scattering device. Hegman grind is also a measure of maximum top size. Laser instruments can report a platy particle's absolute diameter, absolute thickness, or somewhere in between as a function of particle orientation to the light source. Residue specifications are another parameter related to particle size that provides the application's tolerance to coarse particles inherited from the ore or incidental to processing. Residue is typically expressed as a mass percent age or parts per million (ppm) greater than a specific screen mesh size.

The platy shape of kaolin is an important property that influences coverage, gloss, and printability of a coating. There is no agreed industry standard for reporting kaolin particle shape. The platy shape of individual kaolinite particles is expressed as an aspect ratio, which is the average of a particle's diameter divided by its thickness. An average aspect ratio can be reported for a population of particles. Measurement of the average aspect ratio on kaolin is tedious and expensive because a statistically meaningful ratio requires the measurement of a large population of individual particles using a transmission electron microscope or similar instrument (Vander Wood, Pruett, and Boltin 1995). Kaolin producers and consumers take different approaches to approximating aspect ratio. Some use microscopy, others use a combination of surface area and particle-size measurements. IMERYS developed its own proprietary technology for measuring the shape properties of particles. Some manufacturers of laser light-scattering, particle-sizing instruments claim to measure aspect ratio, but these techniques need to compensate for a range of particle orientations and are highly influenced by particle dispersion.

Rheological Properties

The rheological properties of a kaolin-water suspension can be reported as flowability, viscosity concentration, slurry solids, or fluid viscosity at a specific shear rate. Flowability is expressed as a percentage of solids in the minimum amount of water needed to make a dispersed clay system fluid. Viscosity concentration and slurry solids indicate, respectively, the slurry water content at set viscosity and the recommended water content to make a fluid kaolin suspension fit for use when applied to material handling and to a customer's application. Viscosity concentration is reported as percent solids when an optimally dispersed kaolin suspension is made down to 500 centipoise at 100 rpm measured using a No. 3 spindle on a Brookfield viscometer (Brookfield, Middlebrook, Massachusetts), the standard instrument used to measure low-shear viscosity of clay-water suspension. Brookfield viscosity is expressed in centipoise at a specified solids concentration, rotational speed (10 to 100 rpm), and spindle dimension (typically 1 to 3).

The Hercules viscometer (Kaltec Scientific, Inc., Novi, Michigan) is used to measure the high-shear behavior of a clay-water suspension (TAPPI method T-648). The Hercules instrument applies a shear rate from 0 to either 1,100 rpm or 4,400 rpm. The instrument changes the shear rate from 0 rpm to as high as 4,400 rpm and back down to 0 as it measures the torque (from 1×10^4 to 1.8×10^7 dynes-cm) applied to the clay slurry in a sample cup. Results can be reported in centipoise or more commonly, where the pen exits the chart, in "dynes" or rpm. When the torque equals 1.8×10^7 dynes-cm, an rpm value between 0 and 4,400 at 18 dynes is reported. When the torque is below 18 dynes, the dynes at 4,400 rpm are reported.

The solids concentration of the clay slurry is reported with the bob used and the shear rate or shear stress measurement. The

Figure 13. Types of processed kaolin sold in 2002 by producers in Georgia, kt

measurement made by the Hercules viscometer also describes kaolin slurry as Newtonian, dilatant (shear thickening), or thixotropic (shear thinning).

Information published in previous editions of *Industrial Minerals and Rocks* on the subject of high-shear kaolin rheology has focused on the need for kaolin products that are very fluid under the extreme high-shear conditions found under the blade of modern paper blade coaters. However, the evolution of paper-coating technology, combined with a better understanding of how kaolin properties add value to coatings in terms of appearance properties, have changed, to some degree, the premise that premium kaolin products need to have dynes rheology at slurry solids >71%. For example, metered size press (MSP), curtain, and spray coaters no longer apply paper-coating colors using a blade to level the coating onto paper moving at very high speed. The engineering of paper-coating pigments to provide more even coverage at lighter coat weights or to provide higher opacity at heavier coat weights requires some compromise to rheological properties at high shear. High shear viscosity can be increased when features such as higher aspect ratio particles are engineered into kaolin products to improve coverage or when a more tightly controlled particle-size distribution is used to improve light scatter and opacity. Kaolin pigment fluidity, however, does have an important role in enabling the paper coater to maintain a manageable water balance in the coating color relative to machine-drying capabilities and to economically ship kaolin slurry by truck, rail, or ship.

Abrasiveness

Kaolin used as a pigment or functional filler must be soft and non-abrasive to prevent excessive wear on equipment used during processing or application. The abrasiveness of kaolin is typically measured on dispersed slurry at 15% solids using an Einlechner Abrasion Tester (Einlechner, Kissing, Germany) with the measurement result reported as weight of screen loss after a specified number of revolutions (mg loss/100,000 rev). Factors that impact abrasiveness are Mohs hardness of the mineral and particle size. As kaolinite is very soft, the occurrence of hard particles such as quartz and feldspar in the kaolin product will increase its abrasiveness. The top size and median particle size of the kaolin slurry also influence abrasiveness.

TECHNOLOGY

Processing

Kaolin processing is technically complicated and a costly barrier for entry into many markets where purity, consistency, handling characteristics, and appearance are valued properties. Most kaolin processing is performed in the wet state for pigment, functional

filler, and specialty mineral applications. Kaolin processing is typically performed in the dry state for refractory and ceramic applications where bulk chemistry is important but where purity, handling, and appearance characteristics may be less stringent. The USGS tracks worldwide kaolin production by country, how U.S. kaolin is processed, and how kaolin is used for both domestic and export consumption (see, for example, <http://minerals.usgs.gov/minerals/pubs/commodity/clays>). The USGS reports kaolin processing in several categories: airfloat, calcined, delaminated, unprocessed, and water washed (Figure 13). Dry-processed kaolin includes airfloat processed and refractory-grade calcined categories. Wet-processed kaolin includes water-washed, delaminated, and pigment-grade calcined categories. The term *slip* is used in reference to a low-solids kaolin mineral-water suspension that is wet processed to remove impurities or to engineer particle size and related characteristics. The term *slurry* refers to a final product that is a high-solids and dispersed kaolin mineral-water suspension containing chemicals to prevent unwanted particle agglomeration, gelling, settling, or microbiological growth.

Feed Preparation

Blunging is a process where dry-mined kaolin ore is made down into a mineral-water suspension with water in a range of 35% to 70% solids (Murray 1980). The kaolin blunger is simply a tank with an impeller near the bottom. Blunging is the first step in feed preparation for wet-processed sedimentary kaolins and dry-mined primary kaolins. It is not used where kaolin is wet mined with water-jet monitors. Many blungers are located at the head of pipelines that transport clay slip to the processing operation. Pipelines may then extend tens of kilometers, as in the case of the Georgia kaolin operations, or hundreds of kilometers, as in the case of the kaolin operations in the Capim District of northern Brazil.

The purpose of blunging is mechanical disaggregation of the rock to separate particles and chemical addition to keep particles dispersed. There are two facets of chemical dispersion of kaolin particles:

1. pH adjustment to induce a negative charge on both kaolinite particle edges and faces
2. Use of dispersant chemicals to increase the negative charge on mineral surfaces and thereby increase particle repulsion

The choice of pH used to disperse the kaolin slurry is partly dependent on downstream processes utilized for beneficiation. Typically, pH is adjusted to around 6.5 or 7.0 using sodium carbonate (soda ash). Chemical dispersants can be classified as inorganic or organic. Common inorganic dispersants used for kaolin processing include sodium silicate, tetrasodium polyphosphate (TSPP), and sodium hexametaphosphate (SHMP). The most common organic dispersant used in kaolin processing is sodium polyacrylate. The choice of dispersants used for primary dispersion is based on (1) the ability to disperse the kaolin particles, (2) the tolerance by downstream beneficiation processes, and (3) cost. Conley (1996) provides an excellent review of the principles and practices of chemical and mechanical dispersion.

Refining, Degritting, and Desanding

The concentration of kaolin clay from crude is called refining or desanding. The purpose of refining is to concentrate the kaolin minerals from the other major rock-forming minerals by particle-size separation, thereby making it one of the first steps in kaolin beneficiation. Refining is aimed at removing sand- and coarse, silt-sized particles. The particle size target in the refining process largely depends upon the particle-size distribution of nonkaolin mineral

impurities in the ore. Desanding is the first process step when kaolin is extracted from a primary deposit using a monitor, as in the case of the Cornwall and Devon deposits (Pemberton 1989). The term *grit* is used for particles greater than 44 μm (3.25 mesh), so desanding is the process of de-gritting. Kaolin ores that have high kaolin contents, such as commercial sedimentary kaolin in Georgia and Brazil, have de-gritting steps early in the process that are typically performed after bunting.

The processes used for refining are a function of gangue particle size and content. In Cornwall and Devon, where gangue particles are large and the major component of the ore, clay-bearing materials washed from the pit walls collect in sediment ponds near the pit bottoms. Gravel pumps move the clay-bearing materials from the sediment ponds to a spiral classifier or a bucket wheel desander. The spiral classifier is similar to the drag-box (sandbox) used for removing sand from sedimentary kaolin deposits. This process equipment enables coarse sand particles to settle into a concentrate that can be mechanically removed and enables the kaolin slip containing fine particles to overflow the trough and proceed to the next process. Screens are located throughout the kaolin refining and beneficiation process to remove coarse residues. Screens with very coarse mesh size may be utilized after desanding. Fine sand- and silt-sized particles are removed using hydroseparators and hydrocyclones.

Classification and Fractionation

Classification is synonymous with fractionation, the grading of particles too small to be screened according to their size, shape, and density by control of their settling rate through a fluid medium (USBM 1997). The continuous bowl-type decanter centrifuge, a major advance in kaolin processing in the 1930s, permitted the production of >80% <2 μm kaolin pigments used for paper coating (Murray 1980). The decanter centrifuge has a solid-wall bowl containing a helical screw inside the bowl that rotates at a slightly different speed. Sedimentation occurs inside the bowl, and the screw removes the coarse fraction to the discharge on one end of the rotating assembly while the fines-bearing slip discharges over a weir on the opposite side. The disc nozzle centrifuge is another type of centrifuge used for kaolin processing that has a finer cut size for production of ultra-fine kaolin products.

Brightness Beneficiation

Kaolin beneficiation processes include a range of advanced process technologies such as magnetic separation, selective flocculation, flotation, reduced acid leaching, and oxidative bleaching. Physical separation processes, such as magnetic separation, selective flocculation, and flotation, concentrate kaolin while removing nonkaolin particles, the majority of which are discoloring impurities such as iron oxides, iron hydroxides, titania minerals such as anatase, tourmaline, and micas or abrasive impurities such as quartz and feldspar.

The high-intensity magnetic separator (HIMS) has been used in Georgia and Cornwall for kaolin processing since the 1970s (Mills 1977; Clark 1985). Removal of paramagnetic impurities from kaolin requires that a dispersed kaolin slip slowly pass through a high magnetic field with high field gradient and multiple collecting surfaces. The conventional HIMS is an electromagnet that surrounds a central canister that may be 2.1 m (84 in.) or 3.1 m (120 in.) in diameter with an effective depth of about 51 cm (20 in.). The canisters are filled with a matrix of stainless steel wool. In the 1980s, superconducting magnet technology was introduced for processing kaolin. The main benefit of superconducting magnets is their lower energy consumption, smaller size, and higher field strength that is about 5 Tesla versus about 2 Tesla for a conventional HIMS. Super-

conducting HIMSs are further divided into static and reciprocating magnets. The static superconducting magnets use the same operating principles as a conventional HIMS, where the magnetic field acting on the canister is cycled on and off to allow flushing of magnetic impurities from the canister several times per hour when the magnetic field is eliminated. Reciprocating magnets typically have a higher duty cycle because the magnetic field is constant, and a movable dual canister allows one canister to be in the magnetic field while the other canister is flushed to purge captured impurities (Stadtmuller, Goode, and Riches 1988; Stadtmuller et al. 1997).

The objective of selective flocculation is to aggregate specific mineral particles into large agglomerates while leaving the remaining mineral particles in a dispersed state to permit mineral-mineral separation by gravitational settling. All Georgian and some Brazilian wet kaolin processors use selective flocculation to remove anatase, which contains some iron in the natural state. The selective flocculation process developed by Maynard (Maynard, Millman, and Iannicelli [1969] and Maynard [1974]) is the most common process and requires the blunged kaolin slip at approximately pH 6.5 be (1) overdosed with sodium hexametaphosphate and sodium silicate, (2) conditioned with sodium chloride, (3) aged to allow anatase particle aggregation, and (4) flocculated using a water-soluble, strongly anionic, high-molecular-weight polyacrylamide polymer to form anatase flocs that will settle in a thickener. Several improvements have been made to the selective flocculation process including those described by Shi (1986); Behl, Willis, and Young (1996); and Garforth et al. (2000).

Reverse froth flotation was introduced to kaolin processing in the early 1960s (Greene and Duke 1962; Grounds 1964; Cundy 1976; Yoon and Hilderbrand 1986) to remove anatase from sedimentary kaolin ore. Sedimentary kaolin flotation entails adding a carrier such as ground calcium carbonate (ground limestone) or divalent ion such as calcium or barium chloride to a dispersed kaolin slip to aggregate anatase. The slip is then conditioned with a collector such as fatty acid that coats anatase particle surfaces, making these surfaces hydrophobic so that the anatase will attach to air bubbles.

Reduced-acid leaching and oxidative bleaching are chemical treatments applied to kaolin slurries to improve brightness and shade. The use of reduced-acid leaching to remove soluble iron oxides such as hematite and goethite from kaolin slips has been around since the 1930s. Sodium hydrosulfite (sodium dithionite) is added to a clay slip that has been acidified with sulfuric acid to pH of 3. The sodium hydrosulfite creates a reducing chemical environment that promotes the dissolution of iron oxides and iron hydroxides. The low pH keeps the iron in solution until it can be removed in the liquid phase from the clay slip by filters. The dissolution and removal of iron oxide and iron hydroxide minerals that absorb light on the blue portion of the visible light spectrum increase brightness and decrease yellowness. In the 1970s, oxidative bleaching by ozone gas was introduced as a cost-effective method of brightness improvement. The ionization of the oxygen or dry air in the ozone generator creates ozone, which is then bubbled through ozone contact towers that allow the gas to oxidize organic matter contained in the clay slurry.

Wet Grinding and Delamination

Kaolin processors use grinding to reduce particle size and to help obtain mineral liberation for mineral separation processes. Delamination is the cleaving or parting of kaolinite stacks into finer platy particles (Figure 14). During the mid-1950s, the delamination process was initially by extrusion of coarse kaolin. In the late 1950s, the U.S. Bureau of Mines (USBM) developed attrition grinding of

clay slurries using sand or other media to delaminate and separate fine kaolinite platy particles (Feld et al. 1960). Delaminated products show value in paper coating because they have good sheet coverage and printability.

Dewatering

Dispersed kaolin clay slurries are typically shipped by tanker truck, rail, or ship at about 60% to 70% solids, depending on product type. Kaolin slip solids in the processing operation can range from 5% to 70%, depending on mining and blending technology. Kaolin slip solids are typically between 15% and 35% at the leaching stage, which occurs after physical separation of impurities, particle classification, and grinding. Most dewatering technologies require obtaining a flocculated kaolin slip in preparation for reduced-acid leaching. Kaolin particles are flocculated when pH is adjusted to <5 and chemicals such as alum and high molecular weight polymers are added to aid dewatering. Thickeners, centrifuges, rotary vacuum filters, and pressure filters are then used to dewater flocculated slip (Murray 1980; Leung 1988). Dewatering a dispersed kaolin slip is possible with use of centrifuges, membrane filters, evapora-

tors, and back mixing with dried clay. The limitations of filtration technologies and the need to add water to redisperse flocculated slip typically allow only evaporating and back mixing with dry clay to increase slurry solids to 65% to 70%. The spray-dry back-mix process involves addition of spray-dried clay to slurry in a mixing tank in a proportion required to raise slip solids to the appropriate amount for shipping.

Drying

Kaolin can be dried using several types of dryers: spray, rotary, tray, fluid bed, and apron. The spray dryer is the most common dryer technology used by U.S. and Brazilian kaolin producers. Spray drying involves feeding slip to an atomizer located at the top of a heated chamber. Atomized droplets of slip quickly dry into beads about 0.25 to 1 mm in diameter with a moisture content between 1 and 3 wt %. The other dryer technologies previously mentioned are fed undispersed filter cake. The apron dryer is a common process for making acid-lump type products that contain low levels of dispersant. A band conveys a 2.5 to 15 cm (1 to 6 in.) bed of shredded or extruded filter cake on a perforated apron through a tunnel-like chamber containing hot gases. Dried product can be loaded bulk into road, rail, or sea containers or packaged into 50-lb or 1-t bags. Dried product can be milled or pulverized to a powder form to help further reduce moisture content and improve ease of product makedown into slurry for intended applications.

Calcination

Calcination is a thermal process that causes kaolin minerals to transform to other amorphous or crystalline phases. The phase transformations that occur during calcination are the dehydroxylation of kaolinite to metakaolinite at about 500°C and crystallization of metakaolinite into mullite above 1,000°C. Calcination can increase the brightness of kaolin by burning off organic matter and structures the clay into aggregates (Figure 15). Calciners used by the kaolin industry include the horizontal rotary kiln and vertical Herreshoff. Milling is typically used on the calcined product to break up coarse agglomerates and residue.

Georgia Kaolin Processing

Georgia kaolin is most commonly processed in the slurry form by a variety of advanced beneficiation methods (Pruett 2000). Typically, the wet-process plant first blends kaolin from several mines to

enable production of a specific range of products. The kaolin is blunged into slurry that is then centrifuged to make products having a range of particle sizes, which then may be whitened and brightened by chemical reduction leaching, oxidation bleaching, HIMS, selective flocculation, froth flotation, thermal calcination, and other proprietary methods. The refined kaolin products may be shipped to North American customers as high-solids slurry in tank cars or dried for worldwide export. In typical years, approximately two thirds of Georgia kaolin production is used in North America, and one third is exported, mostly to customers in Western Europe and southeastern Asia (Figure 16). About two thirds of the kaolin produced in the Georgia district by wet slurry processing is used as a pigment for coating fine printing papers (Figure 17) for use in magazines, catalogs, and annual reports. These slurry-processed products may also be used as a pigment extender in paints, plastics, adhesives, and sealants; for various ceramic, refractory, and catalyst raw materials; and as an inert binder in pharmaceuticals. Export kaolin products may be shipped in bulk, in polypropylene big-bags, or by large metal shipping containers.

A rather small percentage of Georgia kaolin production (Figure 13), and most of South Carolina's production (374 kt, USGS 2002), is processed by dry air-float methods. Dry processing is less costly than wet processing but is not capable of improving kaolin quality other than by limited removal of grit material. The typical dry-process plant hauls the kaolin from the mines by highway truck and sorts it at the plant into various different crude grades in several separate bins. The different grades of clay are blended as they are loaded into a slicer, which breaks the lumps down to feed a dryer. The dried clay is then transported on a column of rapidly moving air into a roller mill or other dry mill where the clay is pulverized to a powder form. The air column sweeps the powdered clay from the mill through a whizzer or cyclone classifier where coarse sand-size particles can be removed as gangue or returned to the mill for further size reduction. Airfloat processed Georgia and South Carolina kaolins are used for ceramic sanitaryware, dinnerware, and decorative tile; as a pigment extender in floor coverings, paints, insecticide, and herbicide carriers; and as aluminous raw material for fiberglass and portland cement manufacture.

EXPLORATION

Strategy

The most effective exploration for new deposits of commercial grade kaolin is begun by considering how the mineral was originally concentrated, altered, or deposited. The history of a kaolin deposit's formation is a useful indicator of the topography, elevation, structural attitude, degree of alteration, and stratigraphic sequence in which favorable deposits of kaolin are most likely to be discovered.

As examples, the Devon and Cornwall-type hydrothermally altered primary kaolins are typically discovered as alteration deposits along high-angle shear zones or joints in the parent granite and therefore are commonly found in near-vertical funnel-shaped concentrations. Exploration for this type of kaolin takes into consideration the preferred orientation of joint systems that were used by hydrothermal kaolinizing fluids, which cut the types of granitic rocks that tend to be altered to commercial grade kaolin. Knowing that kaolinization occurs in the district to a depth of several hundred meters, a drilling program needs to be prepared to drill to at least that depth.

By contrast, Sparta-type primary kaolin from middle Georgia formed by surficial weathering of the muscovite-biotite granite and therefore occurs as a near-surface pallid saprolite blanket beneath upland divides where the weathering zone has been seasonally wet-

Figure 17. Electron photomicrograph showing a cross-section of coated paper. The very bright lines at the top and base of the paper are kaolin coatings. The bright regions between the coating and darker-colored wood fibers are mineral filler.

ted and dried. By this model, Sparta-type primary kaolins are not expected to occur beneath stream valleys which have been continually water saturated. A drilling strategy for this type of primary kaolin concentrates on shallow exploration and stops coring when the saprolite begins to contain unaltered feldspars from the parent rock.

As a further example, the very productive central Georgia kaolins and eastern Amazon region Brazilian kaolins were deposited in low-energy water bodies associated with a fluvial deltaic sedimentary environment. These kaolin deposits therefore occur as clay lenses scattered in fining-upward sedimentary sequences. The common presence in Georgia of a thick overlying smectitic marine clay unit suggests that exploration needs to be concentrated along elevations where the marine clay cover has been breached by later erosion, allowing fresh groundwater to access the kaolin lenses and to oxidize sulfide minerals and organic matter.

Necessity for Continuous New Exploration

Because most kaolin mining operations require a very large capital investment for processing plant construction and for periodic

Table 6. Typical drill spacing plan for kaolin exploration and mine development

Intent of drilling campaign	Drill hole grid spacing	
	m	ft
Initial exploratory work	120	400
Preliminary proving of reserves	60	200
Preparation for stripping and mining	30	100
Mine quality control	15	50

Table 7. Kaolin pigment grade structure for application in paper coatings. Particle size is reported at the range midpoint as equivalent spherical diameter (esd) using a gravitational settling particle-size analysis method.

Grade	Particle Size, esd
Ultrafine	98 wt %, <2 µm
Fine #1	95 wt %, <2 µm
#1	90 wt %, <2 µm
#2	85 wt %, <2 µm
#3	65 wt %, <2 µm

upgrades, there is a continual need for at least several decades of ore reserves.

Many types of kaolin deposits can be worked to produce quite variable recovery of finished clay products from large tonnages of crude kaolin. As examples, the Devon–Cornwall primary kaolin pits are said to yield 8% to 20% finished product from wet crude ore. At the other extreme, the Rio Jari fine particle size, sedimentary kaolin deposit in northeastern Brazil is reputed to provide product recovery of about 70% finished product from a wet crude ore. Whatever the anticipated recovery for the kaolin district being mined, the exploration manager must continually discover an increasingly large tonnage of proven ore reserves in order to maintain a future clay reserve to support investment in costly new plant and equipment.

Exploration Methods

In areas where core drilling equipment is available, new kaolin deposits are discovered by widely spaced “wildcat” drilling in areas near previously known commercial deposits and at elevations or areas of favorable geology. This initial discovery drilling may be done at drill-hole spacing of 240 m (800 ft) or greater. Once commercial quality kaolin is encountered by this type of drilling, it is customary to have a surveyed grid laid out for carefully spaced drilling to develop an actual mining plan. Typically, this type of sequential development drilling is done by variations of the spacing plan shown in Table 6. In the Georgia kaolin district, typical core drilling equipment is truck-mounted units with integral mud pump equipped with a double-tube core barrel and hard-metal alloy tipped bits. Core may be NX (nominal 2½ in. diameter), which provides sufficient samples for extensive laboratory testing.

Typically, in this type of kaolin exploration, the overburden and nonkaolinitic zones are drilled through by “fishtail” bit without coring. When kaolin cuttings are observed in the drill fluids, the core barrel is inserted into the borehole, and continuous core samples are taken until the clay zone has been completely penetrated. The clay core is forced from the inner barrel by hydraulic pressure from the mud pump. Kaolin core is carefully marked to identify the property drilled, the grid location of the hole, and top and bottom

depths of the interval sampled. The core is then packed in wooden or cardboard boxes, or bagged by depth interval, and transported to the core testing laboratory.

In the core testing laboratory the kaolin is trimmed to remove contamination, analyzed for crude clay quality, and then tested for potential product quality by replicating on the lab bench scale the beneficiation performed in the processing plant. Typically, laboratory tests are done for grit (+325 mesh) residue content, brightness, color, particle size, low- and high-shear viscosity, and for other physical and chemical properties needed by the customer. Testing results are posted on carefully scaled grid maps, which are used as the basis for all mine planning, initial quality control, and reserve calculations.

MINING METHODS

Primary kaolin deposits, with their typical large percentages of coarse grit material, commonly have a soft, mealy texture. This type of primary kaolin is often mined by a “water cannon” or monitor, by which the clay is washed from the bank or highwall by a high-pressure stream of water. The resulting clay slurry flows to the lowest portion of the pit where most coarse grit particles are allowed to settle out from the kaolin slurry, which is pumped through a pipeline to the refinery.

The more-concentrated sedimentary kaolin deposits, which have much lower grit content due to the fluvial process of sedimentary winnowing, are usually mined by dry excavation methods. The open pit mines are laid out from about 1 to 15 hectares (acres) in size, depending on economics, ore zone thickness, and production demand for the exposed kaolin. Overburden is removed by backhoe and large capacity off-road haul trucks, two-motor pan scrapers, or dragline. Pit highwall slopes are usually worked at a 1:1 ratio, or 45 degree angle, and may be as deep as 45 m (150 ft) or even more if necessary. Average overburden to clay ratio may be as high as 4:1 to 8:1, or even higher if the kaolin is of a particularly needed grade.

Many of the deeper kaolin mines may need to contend with large volumes of groundwater, from either perched or artesian water zones. Mine water levels may be controlled by dewatering from a ditch encircling the perimeter of the pit. Excessive ground and surface water is pumped from a sump located in the ditch to an impoundment area where the water is clarified prior to being discharged into nearby streams. Alternatively, dewatering wells can be used to lower the artesian water level in particularly wet and deep kaolin mines.

After excavation, the kaolin is transported from mine to processing plant by two basic methods: as dispersed slurry by pipeline or as solid lump clay by highway haul trucks. The slurry transport system is much less costly after the pipeline cost is amortized, and also saves on fuel costs and potential damage to public roads. Slurry transport of the kaolin has the additional advantage of allowing degritting operations at the mining area, where the grit can be disposed of with overburden.

TRENDS

Production Statistics

The USGS and the China Clay Producers Association (CCPA) compile statistics on worldwide kaolin production. The CCPA statistics (a available from <http://www.kaolin.com>) focus on paper grades produced in Georgia by the four major wet-processed kaolin producers: Engelhard, IMERYS, J.M. Huber, and Thiele Kaolin Company. The CCPA categorizes several grades based on product particle size, brightness, or additional processing. Standard kaolin grades typically have GE brightness between 84 and

89 and specified particle-size ranges (Table 7). High-brightness, paper-coating kaolin typically has GE brightness of >89. Highly processed grades include delaminated, calcined, aggregated, and engineered.

Particle shape and particle-size distribution are properties that are now engineered into many pigments to add functional value in specific market segments or to specific customer needs. These products comprise the engineered grade category. Particle engineering has reduced the importance of the coating kaolin grade structure based on particle size (Table 7) and raised the importance of the pigment's functional performance in the customer's application, much like a specialty chemical (Bundy 1993). The kaolin industry's move to engineered pigments and functional fillers, similar to other engineered industrial minerals, prevents simple commoditization of kaolin into a few grades that fit all consumer needs.

Market Trends

Several factors strongly influence the volumes of kaolin produced to meet global market demands:

- The paper market drives the demand for world production of beneficiated kaolin products (Figure 18). In 2000, about 79% of Georgian production, 90% of Brazilian production, and 75% of Cornish production was for the paper market.
- The growth in kaolin production is mostly related to its use since the 1930s as a pigment to improve the appearance and printability of coated paper and coated paper board (Figures 10 and 18).
- Since the 1940s most paper-coating kaolin has come from sedimentary kaolin ores (Figure 10).
- Kaolin demand for paper filling has fallen since the 1980s. This is seen in the U.S. market, where precipitated calcium carbonate (PCC) has replaced kaolin as the filler of choice in uncoated woodfree (freesheet) paper grades. This choice is paper-mill specific and driven by (1) PCC's high brightness and light-scattering properties relative to regular brightness of hydrous kaolin, (2) the availability of carbon dioxide from the paper mill's lime kiln, and (3) the relative logistics cost of delivered kaolin and lime.
- The kaolin growth rate for paper coating diminished in the late 1990s as European-type coated papers that contain high levels of calcium carbonate gained market share. This change in the growth rate caused the oversupply of kaolin pigments and resulted in some manufacturing shutdowns in the United States and the United Kingdom (Figure 10). The number of wet-processed kaolin producers in Georgia dropped to four from six active companies in the early 1990s. Brazil has continued to grow because of the favorable quality and cost of products produced in the Amazon region.

REGULATORY AND ENVIRONMENTAL CONSIDERATIONS

Health and Safety

Kaolin producers must comply with health and safety regulations. Health regulations enforced by state and federal government bodies cover aspects of worker safety in the mines and process operations. In the United States mine and associated milling and laboratory workplace safety and health is regulated by the U.S. Mine Safety and Health Administration (MSHA). Kaolin operations in the European Union and Brazil also comply with similar strict workplace safety requirements. For example, Brazil requires manufacturers to have on-site medical staff at production operations.

The health and safety of employees working for customers and for the end users are also a concern for kaolin producers.

Kaolin is recognized as a chemically inert material that can be safely used and handled in many applications. Most wet-processed kaolin products comply with U.S. Food and Drug Administration (FDA) or equivalent regulations for use in food contact applications with paper and paperboard. FDA compliance covers the minerals as well as the chemicals used during processing and for slurry preservation, including biocides. Some kaolin products also are designed to meet pharmaceutical or United States Pharmacopeia (USP) regulations where the product may be ingested, as in the case of anti-diarrhea medications. USP regulations determine permissible levels of metals and other compounds in the processed kaolin. Kaolin dust can pose a pulmonary hazard at high levels over extended periods of exposure, and some kaolin products may contain low levels of crystalline silica, such as natural quartz particles. The product material safety data sheets (MSDS) should be consulted when handling any product.

Pollution Control

Kaolin producers invest significant resources on environmental compliance to meet local and federal environmental regulations. Although the mining process disrupts land, mines are reclaimed to their original topography or improved by development of wetlands or ponds. To prevent soil erosion and to recondition the restored soils, mine lands are replanted with grasses. Reclaimed kaolin mine lands in Georgia and Brazil are frequently replanted with trees. In Cornwall, one mined-out pit became the site of the Eden Project, a series of domes that contain flora from different climates and continents.

Emissions from kaolin process operations are strictly controlled. Coarse mineral tailings and slimes from kaolin beneficiation are emptied into impounds that are acidified to flocculate and remove solids. In compliance with water permits, the clarified water discharge from these impounds is chemically neutralized prior to discharge into streams. Air emissions are also strictly controlled by permits that limit the levels of dust, sulfur dioxide, and nitrous oxides discharged into the atmosphere. Environmental compliance is engineered into kaolin process operations, and most

operations make every effort to maximize kaolin recovery to prevent unwanted losses that fill impounds.

Sustainable development is a relatively new term that encompasses the past practices by kaolin producers to carry on long-term stewardship of the land, to maintain a healthy and safe environment for workers and neighbors, and to minimize raw material and energy consumption. The close dependence between local communities and kaolin producers requires continued discourse to resolve issues and maintain productive relationships. Innovation in terms of processing and product development are necessary to maintain the viability of the business relative to competition and increasing costs, as well as to extend reserves to resources once not considered economically useful.

Palygorskite and Sepiolite (Hormites)*

Haydn H. Murray and Huitang Zhou

INTRODUCTION

The hormite clay minerals palygorskite and sepiolite are elongate clays that have many important industrial applications. Important deposits of these clays occur in the United States, China, Senegal, Spain, India, and Ukraine. The majority of the deposits are Miocene in age. Mining is by open-pit methods, and the processing is dry, although there is some wet processing for special applications.

Palygorskite and sepiolite are hydrated magnesium, iron, and aluminum silicates. In the United States, the term *attapulgit* is used in place of palygorskite; however, the International Nomenclature Committee determined that palygorskite is the preferred name (Bailey et al. 1971).

In 1862, Savchenkov used the name “palygorskite” to describe a mineral from the Palygorsk locality in the Ural Mountains (Hay 1975). J. deLapparent proposed the name “attapulgit” for clays from Attapulgis, Georgia, in the United States, and from Mormoiron in France, because he thought them to be different than palygorskite, but Bailey et al. (1971) proved them to be the same.

Both palygorskite and sepiolite are referred to as sorptive clays because of their large surface area and high sorptive capacity. The term *fuller's earth* adds additional complications to the nomenclature. Fuller's earth is more or less a catchall term for clays and other fine-grained earthy materials suitable for bleaching and sorbent uses. It has no compositional or mineralogical meaning. Fuller's earth was first applied to earthy materials used in cleansing and fulling wool, thereby removing lanolin and dirt—thus the name fuller's earth (Robertson 1986). The term “fuller's earth” is used quite often for palygorskite and sepiolite, some smectites, and other sorptive materials. For more detailed information, refer to the chapter on fuller's earth elsewhere in this volume.

Because of the elongate shape of palygorskite and sepiolite, the industrial applications are many and diverse. The elongate shape of the particles prevents flocculation, so these clays are used as suspending agents in systems with high electrolyte concentrations.

MINERALOGY, OCCURRENCE, AND ORIGIN

Mineralogy

Both palygorskite and sepiolite are 2:1 layer silicates, which means that the octahedral layer is bound above and below by a silica tetrahedral sheet. The tetrahedral sheets are linked infinitely in two dimensions. These two minerals are structurally different from other clay minerals in that the octahedral sheets extend in only one dimension and the tetrahedral sheets are divided into ribbons by a periodic inversion of rows of tetrahedrons. Figure 1 shows the structure of palygorskite (attapulgit) and Figure 2 shows the structure of sepiolite; the channels between the ribbon strips are larger in sepiolite than in palygorskite. In palygorskite the dimensions of the channels are approximately 4 Å by 6 Å and in sepiolite the dimensions are about 4 Å by 9.5 Å. Figure 3 shows a scanning electron micrograph (SEM) of palygorskite. The general chemical formula for palygorskite is $\text{Mg}_5(\text{Si}_8\text{O}_{20})(\text{OH})_2(\text{OH}_2)_4 \cdot 4\text{H}_2\text{O}$ and for sepiolite is $\text{Mg}_8(\text{Si}_{12}\text{O}_{30})(\text{OH})_4(\text{OH}_2)_4 \cdot \text{N H}_2\text{O}$.

These two clay minerals contain two types of water—one coordinated to the octahedral cations and the other loosely bonded in the channels. The latter water is referred to as zeolitic water. The channels may also contain exchangeable cations. The elongate morphology and the presence of the channels are the most important physical attributes, which are described later in this chapter.

Palygorskite is more common than sepiolite. Usually, minor quantities of sepiolite are associated with the palygorskite. The major exception is the large sepiolite deposit near Madrid in Spain. Minor minerals in these deposits are smectite, quartz, dolomite, calcite, and occasionally clinoptilolite.

Bradley (1940) determined the structure of palygorskite and Brauner and Preisinger (1956) determined the structure of sepiolite. Merkl (1989) in his study of the palygorskite deposits in south Georgia and north Florida observed two distinct morphological forms: short-length palygorskite and long-length palygorskite. The short form is 2 μm or less, and the long-length form is greater than 10 μm. He determined that the short-length form had a low magnesium content, whereas the long-length form had a high magnesium content.

Origin and Occurrence

The important deposits of palygorskite and sepiolite occur in southeastern United States, China, Senegal, Spain, and Ukraine (Figure 4). All these major deposits are Eocene or Miocene in age. The origin of these deposits is somewhat uncertain, but in

* At the 13th International Clay Conference held in August, 2005, in Tokyo, the International Nomenclature Committee recommended that use of the term “hormites” be discontinued and all future references be replaced with palygorskite and sepiolite. Therefore, this chapter, originally titled “Hormites,” has been renamed “Palygorskite and Sepiolite” and references to hormites throughout the chapter have been replaced with palygorskite and sepiolite.

Figure 1. Structure of palygorskite

Figure 2. Structure of sepiolite

Figure 3. SEM of palygorskite

general most formed in shallow marine lagoons or tidal flats and in supersaline lakes. The magnesium needed to form the palygorskite, sepiolite, and dolomite was apparently introduced by the reaction of detrital material with magnesium-rich brines and salts resulting from the evaporation of the entrapped sea water (Patterson 1974). The palygorskite and sepiolite precipitated in these hypersaline restricted lagoons or lakes. The dolomite formed under conditions in which the amount of aluminum and silicon was less available from the clastic materials that entered the basin (Weaver and Beck 1972).

United States

The palygorskite-rich deposits in south Georgia and north Florida dominate the world's production. The deposits extend from Quincy, Florida, on the south to the Meigs, Georgia, area on the north (Figure 5), about 80 km. The deposition of the palygorskite took place in a shallow water trough that connected the Gulf of Mexico with the Southeast Georgia Embayment on the Atlantic Ocean (Merkl 1989). The seawater in this trough was characterized by fluctuating salinities, and at times the lagoons were closed off from normal circulation. There was sufficient magnesium present to precipitate palygorskite. The mineralogical content changes from dominantly palygorskite in the Quincy–Attapulga District to a mixture of smectite and palygorskite in the northern area around Ochlocknee and Meigs. Millot (1970) believes that smectite is transformed to palygorskite and sepiolite in a saline, alkaline water environment. These Georgia–Florida deposits are early to middle Miocene in age.

The palygorskite-type fuller's earth occurs in two distinct stratigraphic intervals. The younger Meigs Member of early middle Miocene age unconformably overlies the Dogtown Clay Member of late Lower Miocene age (Figure 6). Both of these members are part of the Hawthorne Group. The Meigs Member contains about equal proportions of smectite and short-length palygorskite along with quartz and a small amount of sepiolite, Opal-A, and sporadic amounts of clinoptilolite. In some sections of the deposit, diatoms comprise up to 50% or more of the fabric. The Dogtown Member has longer length palygorskite and minor amounts of quartz, smectite, and dolomite along with trace amounts of pyrite (Merkl 1989). The deposits in the Dogtown Clay Member in the southern district range from 2 m to slightly more than 3 m in thickness. The deposits in the Meigs Member in the northern district near Ochlocknee and Meigs range from 9 to 14 m in thickness.

Sepiolite is mined in small quantities near La Barge Wells, Nevada, about 160 km north west of Las Vegas in the Amargosa Valley. The sepiolite occurs in thin beds less than 1 m thick interbedded with deposits of saponite. These deposits are Pleistocene in age (Papke 1969).

China

Palygorskite is mined and processed in an area located near the provincial boundary of Anhui and Jiangsu near Guanshan and Xuyi, respectively (Figure 7). At the Guanshan deposit, the palygorskite occurs directly beneath a thick basalt. The palygorskite ranges between 3 and 6 m in thickness (Zhou and Murray 2003). The palygorskite in the Guanshan deposit was precipitated in a lacustrine environment as the alteration product of a basaltic ash (Zhou 1996). The deposits are in the upper member of the Huaguoshan Formation, which is Middle Miocene in age (Figure 7). Within the last 20 years, more than 20 high-quality palygorskite deposits have been discovered in the area shown in Figure 7. The Geological Survey of China estimated that there are more than 200 Mt of palygorskite reserves in this area. The mineralogy of these deposits is dominantly

Figure 4. Location of major palygorskite and sepiolite deposits

Figure 5. Location of the south Georgia–north Florida fuller's earth deposits

palygorskite with minor amounts of smectite, quartz, and dolomite. In the Guanshan deposit, the smectite content increases significantly below the palygorskite layer.

Senegal

Palygorskite is mined near the town of Theis, Senegal, which is approximately 100 km east of Dakar. In this area, the palygorskite directly overlies an aluminum phosphate deposit that is also mined.

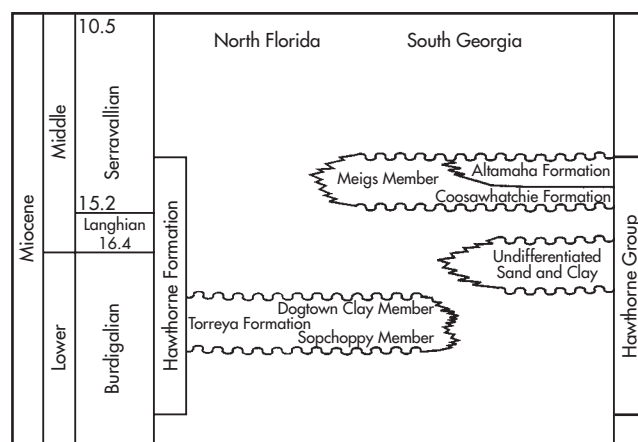

Figure 6. Stratigraphic relationship of the Meigs Clay and Dogtown Clay members

The age of the palygorskite is Early Eocene, and the beds range from 2 to 6 m in thickness (Wirth 1968). The palygorskite is transported by truck to Dakar, and the majority is shipped to Europe. It is estimated that about 400 kt are processed and shipped annually. The palygorskite is used for industrial absorbents, pet litter, and drilling mud mainly in the North Sea. The deposits are palygorskite along with minor amounts of sepiolite, quartz, and dolomite. The palygorskite beds extend south–southwest from Theis to the southern border of Senegal, a distance of about 100 km. The overburden is very thin, usually less than 2 m.

Spain

The world's major commercial sepiolite deposit is located at Vicalvaro near Madrid. The sepiolite was precipitated in Tertiary lakes in an evaporitic sequence (Huertas, Lima res, and Martin-Vivaldi 1971). The thickness ranges from 1 to 5 m. The major uses for this

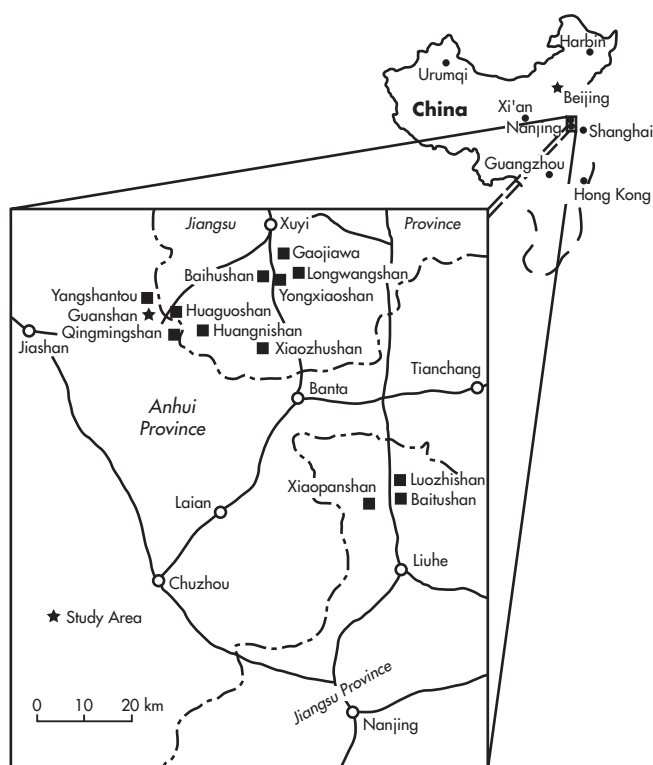

Figure 7. Location of palygorskite deposits in China

sepiolite are pet litter, agricultural carriers, and drilling mud. Approximately 500,000 t are produced annually from the deposits at Vicalvaro. Other locations in Spain producing palygorskite and sepiolite are Toledo, Torreon el Ruhe, Lebija, Almeria, and Maderuelo (Griffiths 1991). Galan (1996) reviewed the properties and applications of these clays and showed the relationship between the structure, composition, and physical properties and their industrial applications. Galan et al. (1976) described a deposit of palygorskite in the province of Caceres. In addition to the applications previously mentioned, palygorskite and sepiolite are used in plastics, mastics, catalysts, bleaching earth, ceramics, and binders for animal feed.

Ukraine

Ovcharenko et al. (1964) described large deposits of palygorskite of Lower Miocene age. Near Kiev, Ukraine, in the Cherkassey District, palygorskite is mined primarily for use in drilling muds. The palygorskite in Ukraine occurs in the central portion of the Ukrainian crystalline massif in the regions near Cherkassey and Kiev. The palygorskite-rich bed occurs in the middle section of a bentonite deposit and is Lower Miocene in age (Ovcharenko and Kuvovsky 1984). The thickness of the palygorskite layer is approximately 2 m. Smectite, hydromica, and quartz are the other mineral constituents in the palygorskite-rich layer.

Other Locations

Palygorskite occurs in Western Australia in a surface deposit at Lake Marromyne. In Turkey, sepiolite is produced near Eskisehir in Anatolia. In Somalia, a deposit of sepiolite is used mainly to produce decorative carvings that are sold to tourists. In Guatemala, there is a deposit of palygorskite about 40 km from the Gulf of Mexico and 30 km south of the Belize border.

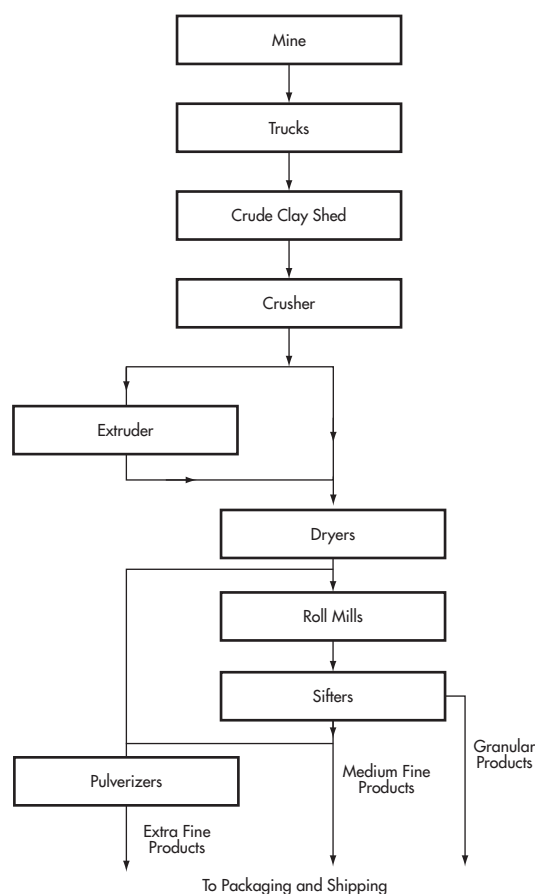

Figure 8. Process flow sheet for palygorskite and sepiolite production

MINING AND PROCESSING

Palygorskite and sepiolite are surface mined. The overburden is stripped with motorized scrapers, draglines, shovels, or bulldozers. The clay is mined using shovels, backhoes, small draglines, or front-end loaders, and is then loaded in trucks that transport the clay to the processing plant. The processing is generally quite simple, involving crushing, drying, classification, and pulverizing. Figure 8 shows a general process flow sheet. Special processes to enhance certain properties are sometimes used, including extrusion to separate the elongate particles; adding 1% or 2% MgO to improve the viscosity for use in drilling muds or thickeners; high heat drying to remove the zeolitic water from the channels in the structure, which produces LVM (low-volatile material) that improves the sorbent properties; and ultrafine pulverization to improve suspension properties and increase the surface area for use in certain pharmaceutical and paint applications. Some palygorskites are acid activated to enhance their bleaching activity for use in clarifying edible and nonedible oils. This acid activation process can be dry, or wet if a superior bleaching earth is required.

Pet litter and agricultural absorbents are granular products that are produced by drying, roll crushing, and screening to a specific granular size. The granular products generally are 15/30, 30/60, and 60/90. This means that the granule passes through the first number and is retained on the second number. A 15/30 product means that all the granules range between 15 and 30 mesh.

PHYSICAL PROPERTIES AND APPLICATIONS

Particle size, shape, distribution, surface area, chemistry, and charge are important physical properties that relate to the application of palygorskite and sepiolite. The properties of these clays that relate to their applications are

- 2:1 layer and inverted structure
- Octahedral substitutions (Mg, Fe, Al)
- Moderate charge on the lattice
- Moderate base exchange capacity (30 to 50 meq/100 g)
- Elongate shape
- Specific gravity 2.0–2.3 g/cm³
- Mohs hardness 2.0–2.5
- High surface area (150 to 320 m²/g)
- High absorption capacity
- High viscosity
- API (American Petroleum Institute) yield—100 to 115 bbl/t

The most important physical property of these clays is their elongate shape, because in many applications it is the controlling property. Considerable substitution of aluminum by magnesium and iron in the octahedral layer gives the particles a moderately high surface charge. This surface charge and the high surface area give the clays a moderate exchange capacity normally ranging from 30 to 50 meq/100 g. The large surface area of more than 100 m²/g, the charge on the lattice, and the periodic inverted silica tetrahedra, which creates parallel channels in the lattice, give palygorskite and sepiolite a high sorptive capacity. These properties, along with the elongate habit of the minerals, make them very useful in many industrial applications. The high viscosity of liquids into which these clays are added is a physical rather than a chemical viscosity, which makes for a very stable suspension viscosity.

The more important industrial applications of palygorskite and sepiolite follow:

- | | |
|-------------------------------|----------------------------|
| • Adhesives | • Laundry washing powders |
| • Agricultural carriers | • Metal drawing lubricants |
| • Animal feed bondants | • Paint and coatings |
| • Anticaking agent | • Paper |
| • Catalyst supports | • Pet litter |
| • Decolorizing oils | • Pharmaceuticals |
| • Drilling fluids | • Polishes |
| • Environmental liners | • Reinforcing fillers |
| • Foundry sand binders | • Suspension fertilizers |
| • Granular carriers | • Tape joint compounds |
| • Industrial floor absorbents | • Wax emulsions |

One of the more important and larger uses is in drilling fluids, where both the viscosity and the gel strength of the mud are not affected by variations in electrolyte content as are drilling muds in which bentonite is used. Palygorskite and sepiolite drilling muds can be used with salt water or when formation brines become a serious problem. The specifications for their use (API Specification 13A) in drilling mud follow. These measurements are made in water containing 40 g of salt (NaCl) per 100 cc of water.

- Viscosity—30 centipoise minimum at 600 rpm
- Yield point/plastic viscosity ratio—3 maximum
- Filtrate volume—15 cm³ maximum
- Residue—75 μ m—4.0 wt % maximum

Table 1. Annual 2004 world production of palygorskite and sepiolite, st

United States	1,200,000
Spain	900,000
Senegal	150,000
China	70,000
India	60,000
Others	100,000
Total	2,480,000

The clays are not flocculated because of their elongate particle shape, and thus they are used as suspending agents and thickeners in paint, medicines, pharmaceuticals, and cosmetics. Ultrafine pulverization to 95% less than 10 μ m substantially improves the suspension properties. Another large use is as floor-sweep compounds that absorb oil and grease spills on factory and service station floors and in other areas where oil and grease spills are a safety problem. Granular clay particles are the most effective type of floor absorbent.

Palygorskite and sepiolite are used extensively in agricultural applications as absorbents and carriers for chemicals and pesticides. High heat drying at a temperature high enough to remove the zeolitic water in the structural channels improves the sorbent properties. The chemical or pesticide is mixed with the clay granules and then placed in the ground with the seed. Tests for absorbent granules are done using the General Services Administration's Federal Specification P-A-1056A. The pesticide or chemical fertilizer is slowly released to provide the necessary protection or fertilizer for the growing plant. Finely pulverized clays are also used to absorb chemicals, which can then be dusted or sprayed on the plant or on the surface of the ground.

Another very large use for palygorskites and sepiolites is pet litter. Granular particles of the clay are an effective litter for absorbing animal waste, particularly for domestic cats. The clay granules absorb the waste and greatly minimize the odors.

Haden (1963) described the properties and applications of palygorskite and pointed out both the colloidal and non-colloidal characteristics that make it an important industrial clay. In the past, palygorskite was used as a catalyst in no carbon required (NCR) paper, but today this is a very minor application. An important future application of palygorskite and sepiolite will be in blends with sodium bentonite in landfill and toxic waste liners or barriers (Keith 2000). The estimated annual world production figure in 2004 totaled more than 2,400,000 st. Table 1 gives a breakdown of this estimate.

FUTURE CONSIDERATIONS AND ENVIRONMENTAL ISSUES

All palygorskite and sepiolite are surface mined and, in most countries, the mining company is required by law to reclaim the land. Common practice is to open a cut, mine the clay, and then spoil the overburden from the next cut into the mined-out area. The spoil is leveled or sloped to meet the standards prescribed by the government, and grasses and/or trees are planted. Sometimes the topsoil is put back on top of the spoil and used for agriculture.

In each of the producing areas described in this chapter, the reserves are substantial, so there is no immediate concern about production in the foreseeable future. Current world production is more than 2 Mt. The markets for both palygorskite and sepiolite will continue to expand in the future. An annual growth rate of 2% to 5% is anticipated.

In the processing plants, the major environmental issue is air quality because of dust. Air quality is maintained by using dust collectors on dryers, pulverizers, baggers, and belt-transfer points. These elongate clays have not been shown to be serious health hazards. Dust, however, if inhaled in considerable amounts day after day, can cause lung problems. Therefore, using dust collectors, face masks, and other devices protects the workers from inhaling too much dust. Most clay dust contains quartz, which is a crystalline silica. Crystalline silica is a suspected carcinogen. Most all of the quartz, however, is 20 µm or larger, which is not in the respirable range of 2 to 10 µm. The small amount of quartz in the respirable range is occluded, which means that the quartz is covered by clay particles, so the crystalline silica does not contact the walls of the lungs. Palygorskite and sepiolite contain no deleterious trace elements or chemical compounds that are hazardous to human health.

Several studies have been made to determine if the elongate clay particles are a possible carcinogen, but to date all the results indicate it is not a carcinogen.

Refractory Clays

Colin C. Harvey, William L. Headrick Jr., and James G. Hemrick

INTRODUCTION

Naturally occurring rocks and clays have served as refractories since they were first used for ovens in China around 30,000 BC. The earliest fired clay refractories appeared later, about 4000 BC. These materials met most industrial needs until the 19th century and the onset of the industrial revolution. This technological transition created a need for better refractories and refractory technology to meet the demands of the growing industries, especially steel manufacturing. As a response to this need, high-purity silica brick and magnesite brick were introduced in the mid-1800s, and carbon and carbon-bonded brick were introduced in the late 1800s. In the United States, the American Ceramic Society was founded in 1899, in part to meet industry demands for improved refractories. Further developments included the introduction of synthetic raw materials in the late 1800s and dolomite bricks in the early 1900s, although their use was limited until the mid-1900s. Synthetic raw materials have since enabled the production of refractories with higher purity and performance, but with higher costs than those produced from mineral raw materials. Today's refractories are produced from minerals, from synthetic raw materials, and from combinations of the two.

Refractory clays are used mainly in making firebricks and blocks of many shapes, insulating bricks, saggars, refractory mortars and mixes, monolithic and castable materials, ramming and air gun mixes, and other products. In Europe and elsewhere, a product called *chamotte* (Anon. 1972a, 1972b) is made by calcining high-grade fire clays and other kaolinitic clays. A similar material produced in the United States is called calcined clay or calcined kaolin. A related material called mullite refractory is made by calcining bauxitic clay or clayey bauxite. Chamotte and calcined clay must be further fabricated into finished refractory products. Considerable tonnages of fire clay have also been previously used in the United States in the manufacture of light-colored face brick, tile, stoneware, and other products.

PRODUCT SPECIFICATIONS

The specifications for refractory clays are as numerous as the different uses. Because resistance to heat is the most essential property, many specifications are based on the heat duty required. Resistance to shrinkage, warping, cracking, and abrasion is also very important in many products, and expressions of the requirements for these properties appear in some specifications. Many of the end products must fulfill rigid dimensional specifications.

Restrictions on raw clay commonly include specifications for plasticity, impurities, and content of alkalis, alkaline earths, and other constituents that reduce fusion points.

GEOLOGY AND MINERALOGY

The mineralogy, occurrence, and origin of refractory kaolin and refractory ball clay are discussed in the companion chapters on kaolins and ball clays in this volume. Consequently, the following discussions concern these topics only as they apply to fire clay.

The degree of ordering of the kaolinite, the principal mineral in fire clay, varies considerably. Most of the kaolinite in the harder and purer varieties of fire clay (also termed *flint clay*) is very well ordered and even more perfectly crystalline than the kaolinite in many kaolins. The kaolinite in the hard fire clay also tends to occur in coarser particles, and in the harder varieties the grains are interlocking. The kaolinite in the plastic varieties of fire clay, however, is ordinarily characterized by imperfectly crystalline structures. The more disordered form of this kaolinite has been widely referred to as fire clay mineral to distinguish it from the more perfectly crystallized forms.

Some of the better grades of refractory clays contain minerals that are richer in aluminum than kaolinite, and, therefore, higher alumina products can be made from them. Some refractory kaolin is a mixture of kaolinite and gibbsite, $\text{Al}(\text{OH})_3 \cdot 3\text{H}_2\text{O}$. The better grades of fire clay, which are exceptionally rich in aluminum, consist of kaolinite and diaspore, $\text{Al}_2\text{Si}_2\text{O}_5(\text{OH})_4 \cdot \text{AlO}(\text{OH})$, and minor quantities of boehmite, $\text{AlO}(\text{OH})$.

OCCURRENCE AND ORIGIN

The physical characteristics of fire clay vary considerably; the clays range from soft and plastic to flintlike (Ryan 1978). Fire clay, therefore, is divisible into plastic, semiplastic, semiflint, and flint types. Flint clay has unique properties for a clay: it lacks plasticity, it breaks with a conchoidal parting into shardlike particles, and most of it is as brittle as limestone. Typical diaspore-bearing flint clay is brittle and has an oolitic, pisolitic, or nodular texture. Such clay is referred to as burley, birdseye, or nodular clay.

Most fire clay occurs in sedimentary rocks, and deposits range in age from Pennsylvanian to Tertiary. Fire clay is particularly common in rocks of Pennsylvanian age, and deposits of this age occur as underclays (seat earths) immediately below or closely associated with coal beds. Fire clays of Cretaceous and Tertiary age often

occur in lenticular bodies. Some deposits of these ages are associated with lignite and are probably underclays, and others have apparently been transported and deposited in local basins in a near-shore, swamp, or floodplain environment.

Opinions differ considerably on the origin of the extensive fire clays occurring below coal beds. Some geologists (Patterson and Hosterman 1963) believe that most underclay deposits formed mainly by the alteration of aluminous sediments in a swampy environment. Some mineralogists, however, believe that these clays were transported and some sort of a sedimentary winnowing process caused the rather pure accumulations of kaolinite in fire clay. Some clays of Cretaceous and Tertiary age were transported and formed by a process similar to those thought to have formed the transported kaolin deposits.

DISTRIBUTION OF DEPOSITS

United States

Fire clay of Pennsylvanian age is widely scattered throughout the Appalachian region and parts of the Mississippi Valley (Anon. 1967). The very-high-quality diaspore-bearing clay and other grades of fire clay occur in the Clearfield District, Pennsylvania, and in the Ozark region in Missouri (Keller 1952). High-grade kaolinitic flint clay and semiflint clays are mined in the Olive Hill District, Kentucky (Patterson and Hosterman 1963); Oak Hill District, Ohio (Stout 1923); and Somerset District, Pennsylvania (Hosterman et al. 1968). Major districts producing fire clay suitable for low- and moderate-heat-duty refractory products include the Allegheny Valley and Beaver Valley districts, Pennsylvania; Cordova District, Alabama; East Liverpool District, Ohio and West Virginia; and the Tuscarawas Valley and Hocking Valley districts, Ohio (Hosterman et al. 1968); and a region that includes parts of Monroe, Audrain, Callaway, and Montgomery counties, Missouri (McQueen 1943).

The largest and best quality fire clay deposits in the Rocky Mountain region are in Fremont, Pueblo, Custer, Huerfano, Jefferson, and Las Animas counties in Colorado. These deposits are in the Purgatoire Formation and Dakota Sandstone of Cretaceous age (Waagé 1953). Fire clay in these deposits occurs as isolated tabular lenses ranging in thickness from 1 to 6 m.

In addition to the fire clay mentioned in the foregoing discussions, other deposits are scattered throughout the western states (Van Sant 1959, 1964; Mark 1963; Anon. 1967). These deposits are of several types, and they include transported, residual, and hydrothermally formed clay. Districts in which these scattered deposits occur include several areas in King County and the Castle Rock area in Cowlitz County, Washington; the Molalla and Hobart Butte areas, Oregon; and the Alberhill area, California. Most of these deposits are of Cenozoic age. Refractory kaolin is produced primarily in the following districts: (1) Georgia–South Carolina kaolin belt; (2) Andersonville, Georgia (Anon. 1972b); (3) Eufaula, Alabama; (4) Arkansas bauxite region; (5) scattered districts in Texas; (6) Latah County, Idaho; and (7) Ione, California (Anon. 1972a). Refractory ball clay is produced primarily in the western parts of Kentucky and Tennessee, but some of the ball clay produced in Texas can be used in refractory products.

The total refractory clay resources in the United States suitable for low-heat-duty refractory products were estimated to be as much as 7 Gt in the 1960s (Hosterman et al. 1968). Since then, however, the decrease in production of many kiln-based industries has led to a steady decrease in demand. In addition, the reserves of high-quality refractory raw materials have been depleted. The clays that can now be mined and processed at competitive costs are suitable only for low-heat-duty products and total less than 1 Gt. The

reserves are primarily in the fire clay and refractory kaolin and ball clay districts outlined previously. A few remaining resources of high-grade diaspore clay are mainly under considerable overburden in Pennsylvania, and only small resources are present in Missouri. The bauxitic kaolin resources are primarily in the Arkansas bauxite region and the Eufaula, Alabama, and Andersonville, Georgia, districts. Some deposits also occur in other parts of Alabama and Georgia.

Other Countries

Refractory clays are produced in many countries; the information available on worldwide production is, however, sketchy and incomplete. This is partly because the distinction between fire clay and miscellaneous clay is not made in some countries, and clay used for refractory products is lumped with kaolin in others.

Those countries that produce more than 1 Mtpy of refractory (fire) clay include Germany, Japan, India, the People's Republic of China, and the United Kingdom. The production in France exceeded 1 Mtpy a few years ago, but has apparently dropped below this figure in recent years. Other countries producing 100,000 tpy to 1 Mtpy include Argentina, Australia, India, Italy, Mexico, Sweden, the United Arab Republic, Uruguay, and Yugoslavia. Refractory clay is exported from the People's Republic of China. Fire clay is also mined in the former Soviet Union and Czechoslovakia, Hungary, Poland, and other Eastern European countries.

As in the United States, fire clay in other countries is in several types of deposits. Kaolinitic fire clay associated with coal beds of Carboniferous age is mined in France, Germany, the United Kingdom, and elsewhere. Very high alumina diaspore bearing flint clays are sources of refractory materials in Israel, the People's Republic of China, Scotland, and South Africa. Refractory kaolin is mined in Australia, Japan, India, Hungary, Italy, Czechoslovakia, Poland, Sweden, Yugoslavia, Mexico, Argentina, Brazil, Chile, Peru, the Republic of South Africa, the United Arab Republic, Iran, and other countries; most such deposits are no older than Cretaceous.

EXPLORATION AND EVALUATION

The methods used in exploring and evaluating fire clay deposits are in general similar to those used for bentonite and kaolin, except that different drilling and testing procedures are required. Drilling fire clay deposits, particularly those of Pennsylvanian age, ordinarily requires diamond bits and core barrels of the type used for minerals in hard rock. This is because the clay itself and the rocks overlying the deposits are hard.

The most common test in evaluating fire clay is determining pyrometric cone equivalence (PCE). For refractory applications, the pyrometric cone measures the combined effects of temperature and time (Klinefelter and Hamlin 1957; Norton 1968). This technique is widely used and consists of series of cones manufactured from various proportions of standard raw materials that will distort at known temperatures. These cones, which consist of a series of standardized unfired ceramic compositions molded into the shape of triangular pyramids, are used to calibrate performance of both refractories and ceramic ware within furnaces. The sample of kaolin is molded into the standard cone shape and is heated along with several standard cones so that its end point can be determined in terms of an equivalent cone number. ASTM test method C24-56 gives the procedure of making this PCE test (Anon. 1972a, 1972b). Other commonly used tests for refractory clays include chemical analysis for soluble sulfate, because only very low levels can be tolerated in refractory products.

In addition to the PCE requirement, fired test pieces also may be tested for such properties as high-temperature stability, hot

strength, porosity, and spalling (Norton 1968; Anon.1972b). Chemical analyses are also required for some evaluations, and the contents of alkalis, alkaline earths, iron oxides, and a few less common elements are critical because they act as fluxes when clay refractories are heated.

PREPARATION FOR MARKETS

Fire clay and other refractory clays are mined by methods similar to those used for other types of clay. A much higher percentage of fire clay mining in the past, however, was underground. Underground mining was used where higher quality clays occurred at considerable depths or where overlying rocks were too hard to strip profitably. Little if any underground mining is now undertaken for refractory clays in the United States, but it is still widely practiced in developing countries throughout the world.

Firebrick and related products are prepared for markets by grinding the clay, shaping or forming the firebrick or other products, and firing (Figure 1). Commonly several varieties of fire clay and grog (crushed, previously fired clay) are blended to make a mix desired for a certain product, and blends are varied considerably to prepare different grades of firebrick. The harder clays are ordinarily the most refractory, and because they lack plasticity, small proportions of kaolin or plastic fire clay or both are added to aid in forming and bonding the brick until firing. Most firebrick is formed by hydraulic or other mechanical presses, but several types of products are intricately shaped and must be formed by hand.

Most firebrick is fired in tunnel kilns heated by gas or oil. A few plants, particularly those making specially shaped products or having a limited market, use downdraft kilns. Finished products are palletized and shipped by rail or truck. Overseas shipments require heavy crating with padded packaging. Calcined clay is ordinarily fired in rotary kilns and shipped in paper bags and in bulk carloads.

APPLICATIONS OF REFRACTORIES

Refractories are used to line furnaces, kilns, smelters, chemical reactor vessels, and gasifiers. By definition they are resistant to heat and chemical and mechanical attack. Refractories are designed to meet the needs of the many industries using them with different classes and grades of refractories produced to meet each industry's demand. Important properties of refractories are heat resistance; chemical inertness; resistance to mechanical and thermal stress and strain (especially thermal shock); resistance to corrosion and erosion by solids, entrained particulates, liquids and gases; resistance to impact; permeability; and many other properties whose importance varies according to the use of the refractory (Schacht 2004).

Refractory materials are used throughout the many industries of the world as in insulation or containment vessel linings in high-temperature and corrosive environments (Carneglia and Barna 1992). They must not only be capable of performing these tasks at elevated temperatures but also may be called on to bear mechanical and thermal loads. These materials are so essential that it would be difficult to identify an industrial process that does not use refractory materials in one aspect or another. Refractories are characterized by two aspects that qualify them as strategic materials: (1) their ability to contain heat, chemicals, and melts; and (2) the crosscutting nature of their utility. Figure 2 shows the ranges of usage temperatures for numerous industrial applications of refractories.

CURRENT FURNACE TECHNOLOGIES

Many different types of furnaces are used in United States industries, with different refractory types and issues prevalent for each type. Fifteen classifications of furnaces can be identified, with common issues for each type: blast furnaces; basic oxygen fur-

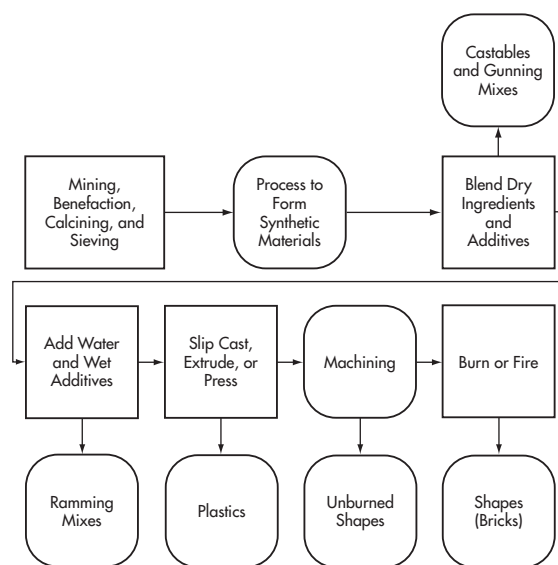

Figure 1. Steps in refractory production

naces; reverberatory furnaces; multiple hearth furnaces; transfer vessels (i.e., ladles, tundishes, troughs, runners); electrolytic smelters; kilns and calciners; electric arc furnaces; cupolas; heat treatment or annealing furnaces and drying ovens; stills and retorts; reactors, reformers, and refiners; steam boilers and incinerators; gasifiers; and heat exchangers. Table 1 lists typical industrial applications of these 15 furnace types. Table 2 lists refractory challenges and problems related to these furnace types, as reported by industry personnel.

REFRACTORY USAGE IN INDUSTRY

Although refractories are used in most, if not all, of the industries in the United States, the iron and steel industry consumes 70% of the refractories used, whereas the cement and lime industry consumes 7%, the ceramics industry 6%, the glass industry 3% to 4%, and the oil industry about 4%. According to U.S. Geological Survey (USGS) census figures, 400,000 t of refractory clay were shipped in 2003.

The most widely used raw materials for the production of refractories are listed in the sections that follow, along with some of their advantages and disadvantages. Many minerals make up each group of raw materials. Refractory raw materials are generally classified as acidic, neutral, or basic depending on the primary component.

Classification of Refractory Minerals

Refractory minerals containing aluminosilicates are acidic; those made of magnesia or calcia are basic; and others, primarily containing alumina, are neutral. These classifications are derived from historical slag practices in the metal industries. The following is a list of refractory minerals with their classifications.

- Zircon (ZrSiO_4): acidic; found in silica sands; used for glass contact refractories because of its resistance to molten glass
- Quartzite (SiO_2): acidic; used for roofs of furnaces where high strength and refractoriness are necessary (silica refractories are poor in thermal shock and alkali resistance)
- Fire clay ($[\text{x}]\text{Al}_2\text{O}_3 \cdot [1-\text{x}]\text{SiO}_2$): acidic; 30% to 45% alumina (Al_2O_3), includes andalusite (Al_2SiO_5), flint clay, pyrophyllite ($\text{AlSi}_2\text{O}_5\text{OH}$); the most widely used refractory raw material

Heat exchangers	X							X

- Sillimanite and kyanite (Al_2SiO_5): acidic; used at higher temperatures than those at which fire clay can be used for tile and casting mixes
- Bauxite ($[\text{x}]\text{Al}_2\text{O}_3 \cdot [1-\text{x}]\text{H}_2\text{O}$): neutral; most widely used for alumina production; made up of gibbsite ($\text{Al}(\text{OH})_3$), boehmite ($\text{AlO}(\text{OH})$), and diaspore ($\text{AlO}(\text{OH})$); used at higher temperatures than those at which sillimanite-based refractories can be used
- Chromite ($\text{FeO} \cdot \text{Cr}_2\text{O}_3$): neutral; used as a buffer between acidic and basic refractories
- Magnesite (MgCO_3): basic; generally used in ferrous metal industries
- Dolomite ($\text{CaMg}(\text{CO}_3)_2$): basic; generally used in ferrous metal industries; more susceptible to hydration than magnesite
- Graphite (C): naturally occurring form of carbon; nonwetting and resistant to chemical attack, but oxidizes

Synthetic Raw Materials Used for Refractory Production

Synthetic raw materials have enabled the production of improved refractories with higher purities, but these cost more than refractories produced from mineral raw materials. The most widely used synthetic materials for the production of refractories are as follows, including generalities of their advantages and disadvantages.

- Alumina (Al_2O_3): neutral; produced from bauxite, aluminum salts, and aluminum metal; one of the most used and studied refractory materials; other materials are generally compared to alumina
- Mullite ($\text{Al}_4\text{Si}_1.5\text{O}_{9.75}$): neutral; produced from kyanite ($\text{Al}_2\text{O}_3 \cdot \text{SiO}_2$), kaolinite ($\text{Al}_2\text{Si}_2\text{O}_5(\text{OH})_4$), or various combinations of alumina- and silica-containing raw materials; theoretically, 72% Al_2O_3 , but commercially available grades range from 47% to 85% Al_2O_3

- Spinel (MgAl_2O_4): neutral; produced from alumina (Al_2O_3) and magnesia (MgO); synthesized using a wide range of raw materials and techniques; theoretically, 72% Al_2O_3 , but commercially available grades range from 65% to 90% Al_2O_3 ; more corrosion resistant than alumina in many instances without the hydration problems of dolomite ($\text{CaO} \cdot \text{MgO}$) or magnesia (MgO)
- Calcium aluminate cement ($[\text{x}]\text{CaO} \cdot [1-\text{x}]\text{Al}_2\text{O}_3$): neutral to basic; produced from lime (CaO) and alumina blended in many ratios depending on the desired alumina ratio; hydratable binder used for most refractory castables; other binder systems include colloidal silica (SiO_2), sodium silicate ($\text{Na}_2\text{O} \cdot \text{SiO}_2$), and phosphoric acid (H_3PO_4), among others
- Silicon carbide (SiC): produced from silica sand and coke; very hard material used in load-bearing and abrasion-resistance applications; very high thermal conductivity
- Boron carbide (B_4C): rarely used for refractories except in instances where higher abrasion resistance is needed than with refractory grade silicon carbide
- Silicon nitride (Si_3N_4): similar in properties and use to silicon carbide but generally more resistant to oxidation and thermal shock
- Boron nitride (BN): often used as a lubricant, a seal, and an antiwetting agent; two crystal forms similar to carbon; hexagonal flakes like graphite and cubic like diamond

Production Techniques and Finished Refractory Materials

The American Society for Testing and Materials (ASTM) classifies refractories according to forming technique and chemistry. The production technique is tied to the forming technique and chemistry of the refractory. General production follows the steps shown in

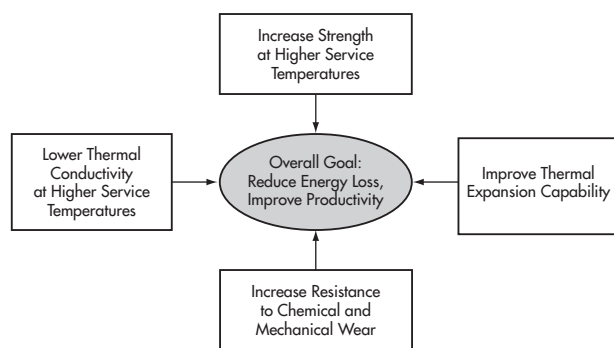

Figure 3. Improving refractory materials for improved energy efficiency

Figure 3. Those materials that do not pass quality control at any point in the process are crushed and sieved to form synthetic raw materials.

The following classifications are for shaped refractories (all ASTM standard classifications are available at <http://www.astm.org>):

- C27-98, Standard Classification of Fireclay and High-Alumina Refractory Brick
 - C155-97, Standard Classification of Insulating Firebrick
 - C1547-02, Standard Classification for Fusion-Cast Refractory Blocks and Shapes
 - C416-97, Standard Classification of Silica Refractory Brick
 - C455-97, Standard Classification of Chrome Brick, Chrome-Magnesia Brick, Magnesite-Chrome Brick, and Magnesite Brick
 - C467-97, Standard Classification of Mullite Refractories
 - C545-97, Standard Classification of Zircon Refractories
- The following classifications are for unshaped refractories:
- C673-97, Standard Classification of Fireclay and High-Alumina Plastic Refractories and Ramming Mixes
 - C401-91, Standard Classification of Alumina and Alumina-Silicate Castable Refractories

GOVERNMENT, ENVIRONMENT, AND HEALTH CONSIDERATIONS

Crystalline silica, asbestos, hexavalent chrome, formaldehyde, and the introduced regulations on maximum allowable control technology (MACT) are the greatest government, environmental, and health concerns facing the refractories industry today. The following discusses these concerns and what refractory companies are doing to alleviate them.

Crystalline silica exposure is the single greatest government and health-related issue facing refractory producers because it is found in abundance in almost all refractory raw materials. Therefore, refractory companies are working to reduce dust exposure to reduce the threat of crystalline silica-related health concerns (Crolius 2005).

Asbestos use has declined to near zero because of prevalent health concerns. Many refractory companies are eliminating vermiculite and other asbestos-containing raw materials from their products because of their small asbestos content.

Hexavalent chrome also continues to be a problem for refractory producers. During use, hexavalent chrome may be produced from chrome-containing refractories. Therefore, chrome

use in refractories has drastically fallen because of health concerns, and companies continue to try to eliminate chrome in their products.

Formaldehyde is a small but looming problem, because it is used in many refractory binder systems. The extent of the formaldehyde problem may change in the coming years as its effect on health is better understood or if current regulations are changed.

MACT is the Environmental Protection Agency's plan to limit air pollutants, thus improving the environment. New facilities will need to be constructed and existing facilities may have to retrofit to meet these guidelines.

Of these considerations, crystalline silica is the greatest concern to the refractories industry because most refractories today contain crystalline silica. It is important that refractory material suppliers, producers, and end users work together to alleviate these concerns.

RESEARCH AND DEVELOPMENT

Recent Research

Substantial changes that have occurred in refractories technology over the past 25 years have resulted in crosscutting impacts (issues common to many applications) on a number of the manufacturing industries (Freitag and Richerson 1998). Some of these have included reduction of energy consumption in heat-treating furnaces by (1) the use of fibrous and high-strength porous insulation; (2) the use of resin-bonded MgO-C-metal linings in basic oxygen furnaces in the steel industry, which have greatly extended the number of heats between needed relinings; (3) the use of SiC-based refractories in steel blast furnaces, which has led to increased furnace life; (4) the advent of oxyfuel melting leading to renewed interest in alternative refractory materials in the glass industry, which will allow for processing at higher temperatures and greater corrosion resistance to high alkali and water-rich environments; and (5) the development of many ceramic compositions that have received limited evaluation but have not reached maturity or production status. All these events are representative of industrial process improvements that can be accomplished through advances in refractory materials, yet additional improvements are still possible, which could lead to substantial energy savings throughout the various industries.

Future Research

Evaluation of refractory usage and the barriers and needs of energy-intensive process industries shows several common themes concerning improving refractory materials to improve energy efficiency. These themes relate to reducing energy loss and increasing productivity by developing higher-strength refractories capable of operating at higher temperatures, developing refractories with lower thermal conductivity to reduce wall losses at higher service temperatures, improving the thermal expansion capabilities of current refractories, and developing refractories with greater resistance to chemical and mechanical wear (such as corrosion, erosion, and abrasion). This is conceptualized in Figure 3.

Many issues appear common to multiple industries, as shown by an analysis of current refractory use, current barriers, possible improvements in process energy efficiency, and R&D needs. The following research focus areas and technical R&D topics have been identified as issues common to many applications of refractories.

- *Degradation mechanisms of refractories in different environments.* Further work is needed to determine the mechanisms responsible for the chemical and mechanical degradation of refractories in the various environments in which they are called to operate.

- *Thermal control.* Advances in thermomechanical properties of refractory materials allow furnaces to operate with longer campaigns and with higher levels of insulation for reducing heat losses.
- *Thermomechanical properties at elevated temperature.* Determination of key properties of refractories at elevated temperatures, including elastic modulus, strength, creep behavior, physical and thermal stability resistance, dimensional changes (thermal expansion and changes due to chemical alteration), and thermal conductivity, is needed.

Diamonds

W. Dan Hausel

INTRODUCTION

Diamond is an extraordinary mineral with extreme hardness and inherent beauty that is sought for personal adornment and industrial use. Because the genesis of this unique mineral requires extreme temperature and pressure, natural diamond is rare—so rare that some diamonds are the most valuable commodity on earth, based on weight.

Diamonds are mined on several continents. The value of the raw production has resulted in a multi-billion-dollar industry. Natural diamond production annually averages more than 110 million carats, valued at more than \$7 billion for the raw stones. Diamond values dramatically increase following the fashioning of the stones, and the value again dramatically increases with their dressing in jewelry, such that diamond jewelry typically sells for 10 to 100 times the value of the raw stone. Industrial diamonds, which are of considerably lower value, include synthetic industrial diamonds. Synthetic industrial diamond production has an average annual value of about \$1 billion.

MINERALOGY

Diamond consists simply of carbon. In nature, native carbon may occur as one of the following polymorphs: diamond, graphite, or lonsdaleite (Erllich and Hausel 2002). The physical differences among these polymorphs reflect the different bonds between the carbon atoms in the crystal structure. In diamond, the coordination of the carbon atoms is tetrahedral with each atom held to four others by strong covalent bonds, resulting in a mineral with extreme hardness.

In contrast, graphite has six-member hexagonal carbon rings that resonate between single- and double-shared electron bonds. These graphite sheets are very strong, but the hexagonal rings are stacked and do not share electrons between adjacent sheets, only a residual electrical charge—thus, no chemical bonds occur between the sheets, resulting in graphite being soft and the sheets easily separated.

The hexagonal modification of diamond, known as lonsdaleite, has a closer -packed arrangement of atoms than diamond or graphite, resulting in a rare mineral of extreme hardness (Lonsdale 1971). Lonsdaleite was initially synthesized at temperatures greater than 1,000°C (1,830°F) under static pressures exceeding 130 kbar (Bundy and Kasper 1967). DuPont de Nemours and Co. obtained the same transformation by intense shock compression and thermal

quenching. Lonsdaleite has since been identified in meteorites and in rare unconventional host rocks, the most notable being the Popigay Depression in Siberia (Erllich and Hausel 2002). The extreme hardness of lonsdaleite makes it ideal for industrial grinding, but its rarity makes it unattractive for commercial use.

Crystal Habit

Diamonds are isometric with cubic, octahedral, hexoctahedral, dodecahedral, trisoctahedral, and related habits. Twinning along the octahedral {111} plane is common, and many crystals are often flattened parallel to this plane, producing a habit that appears as flattened, triangular-shaped diamond known as a *macle*.

Cube

Cubes are a relatively uncommon habit for diamond, and when found are primarily frosted industrial stones. Many have been found in placers in Brazil, and a significant percentage of diamonds in the Snap Lake kimberlites of Canada have cubic habit (Pokhilenko et al. 2003). Crystal faces of a cube often exhibit square-shaped pyramidal depressions rotated 45° diagonally to the edge of the crystal face. The cube may also include scattered trigons mixed with pyramidal and other depressions of hexagonal morphology visible with a microscope.

Octahedron

The octahedron is an eight-sided crystal that has the appearance of 2 four-sided pyramids attached at a common base. Each pyramid contains four equilateral triangles known as octahedral faces. In nature, an octahedral face will often have positive or negative trigons—small equilateral triangles that are visible under a microscope. These are growths or etches on the crystal surface that represent disequilibrium during transport to the earth's surface from the initial stable conditions at depth within the mantle.

Partial resorption of the octahedron will result in different crystal habits, including a rounded dodecahedron (12-sided) with rhombic faces. Further resorption may result in ridges on the rhombic faces, yielding a 24-sided crystal known as a *trishexahedron*. Many diamonds from Argyle, Australia; Murfreesboro, Arkansas; and the Colorado–Wyoming State Line District exhibit resorbed crystal habits. Four-sided tetrahedral diamonds are sometimes encountered that are distorted octahedrons (Orlov 1977; Bruton 1979).

Diamonds commonly enclose mineral inclusions along cleavage planes. These tiny inclusions provide important data on the origin of diamond and can be used to determine the age of the stone or to identify the unique chemistry associated with the genesis of diamond.

Bort

Bort is poor-grade diamond used as an industrial abrasive. It forms rounded grains with a rough exterior and has a radiating crystal habit. The term is also applied to diamonds of inferior quality and to small diamond fragments.

Carbonado

Carbonado is a black to grayish, opaque, fine-grained aggregate of microscopic diamond, graphite, and amorphous carbon with or without accessory minerals. The material is hard, occurs mainly as irregular porous concretions and dendritic aggregates of minute octahedra, and sometimes forms regular, globular concretions. Carbonado is characterized by large aggregates (averaging 8 to 12 mm in diameter) that commonly weigh as much as 20 carats. Specimens of several hundred carats are not uncommon. The density for carbonado is less than that for diamond and varies from 3.13 to 3.46 gm/cm³.

Although carbonado had been found in placers in Brazil and Russia, it was not until the 1990s that it was found in situ. Twenty-six grains of carbonado ranging in size from 0.1 to 1 mm were recovered from a 330-lb sample taken from a vachite (a specific type of basalt from the Avacha volcano of eastern Kamchatka) (Smishlyaev 1999; Erlich and Hausel 2002).

Physical Properties of Diamond

Diamond exhibits perfect octahedral cleavage with conchoidal fracture. The mineral is brittle and will easily break with a mild strike of a hammer. Even so, it is the hardest of all naturally occurring minerals and is assigned a hardness of 10 on the Mohs scale and nearly 8,000 kg/mm² on the Knoop scale. Corundum, the next hardest naturally occurring mineral, has a Mohs hardness of 9. Even so, corundum does not even compare to diamond and only has a Knoop scale hardness of 1,370 kg/mm². Because of diamond's extreme hardness and excellent transparency, diamond is extensively used in jewelry and has a variety of industrial uses.

Diamond's hardness varies in different crystallographic directions. This allows for the mineral to be polished with less difficulty in specific directions using diamond powder. For example, it is less difficult to grind the octahedral corners of the diamond, whereas grinding parallel to the octahedral face is nearly impossible.

With perfect cleavage in four directions parallel to the octahedral faces, an octahedron can be fashioned from an irregular diamond by cleaving (Orlov 1977). The specific gravity of diamond (3.516 to 3.525) is high enough that the gem will concentrate in placers with "black sand." This density is surprisingly high, given that it is composed of such a light element. Compared to graphite, diamond is twice as dense because of the close packing of atoms.

Color

Diamonds occur in a variety of colors, including white to colorless and shades of yellow, red, pink, orange, green, blue, brown, gray, and black. Those that are strongly colored are termed *fancies*. Colored diamonds have included some spectacular stones. For example, at the 1989 Christie's Auction in New York, a 3.14-carat Argyle pink sold for \$1.5 million. More recently, a 0.95-carat fancy purplish red Argyle diamond sold for nearly \$1 million. The world's largest faceted diamond, a yellow-brown fancy known as the 545.7-carat

Golden Jubilee (Harlow 1998), is considered priceless. Possibly the most famous diamond in the world, the 45-carat Hope, is a blue fancy.

In most other gemstones, color is the result of minor transition element impurities; however, this is not the case for diamond. Color in many diamonds is related to nitrogen and boron impurities or is the result of structural defects. Diamonds with dispersed nitrogen may produce yellow (canary) gemstones. If the diamond contains some boron, it may be blue, such as the Hope diamond. The Hope was found in India; however, many natural blue diamonds have come from the Premier mine in South Africa. Blue diamonds with traces of boron are referred to as type IIb diamonds and are semiconductors. Natural irradiation may also result in blue coloration in some diamonds (Harlow 1998).

The most common color for diamond is brown. Before the development of the Argyle mine in Australia in 1986, brown diamonds were considered industrial stones. But because of Australian marketing strategies, brown diamonds are now highly prized gems. The lighter brown stones are labeled champagne and the darker brown referred to as cognac. Yellow is the second most common color, and such stones are referred to as Cape diamonds in reference to the Cape Province of South Africa. When the yellow color is intense, the stone is referred to as canary.

Pink, red, and purple diamonds are rare. The color in these is concentrated in tiny lamellae (referred to as pink graining) in an otherwise colorless diamond. The color lamellae are thought to be the result of deformation of the diamond structure.

Even though there are many green diamonds, few are faceted, primarily because most have a thin green surface layer covering clear diamond that is removed during faceting. Faceted green diamonds are so rare that only one is relatively well known (the 41-carat Dresden Green), and is thought to have either originated in India or Brazil. The color in most green diamonds is the result of natural irradiation. Other green diamonds may result from hydrogen impurities. Another variety, known as a green transmitter, produces strong fluorescence that tends to mask the yellow color of the stone. Other colors include rare orange and violet diamonds (Harlow 1998).

One of the better-known black diamonds is the 67.5-carat Orlov. Black diamonds are colored by numerous graphite inclusions, which also make the diamond an electrical conductor. These are difficult to polish because of abundant soft graphite, so black gem diamonds are uncommon. Opalescent, or fancy milky white diamond is the result of numerous mineral inclusions and possibly nitrogen defects in the crystal (Harlow 1998).

Dispersion, Transparency, Conductivity, Wet Ability

Diamond has a high coefficient of dispersion (0.044), the coefficient is the difference in refractive index of two visible light wavelengths at the opposite ends of the spectrum (one blue-violet and the other red), resulting in the distinct fire seen in faceted diamond caused by its high dispersion. Diamond is completely transparent to a broad segment of the electromagnetic spectrum, making it useful in a variety of industrial, electrical, and scientific applications. It is also transparent to radio and microwaves. Colorless diamonds are also transparent to visible light wavelengths extending into the ultraviolet (UV), and a few rare diamonds (type II) are transparent over much of the UV spectrum (Harlow 1998).

Diamond has a luster described as greasy to adamantine that is related to its high refractive index (IR = 2.4195) and density. Such high density greatly diminishes the speed of light. For example, the speed of light in a vacuum is 186,000 miles/sec (300,000 km/sec), but in diamond, it is only 77,000 miles/sec (Harlow 1998).

Many diamonds are luminescent: approximately one third of all diamonds luminesce blue when placed in UV light. In most cases, luminescence will stop when the UV light is turned off (known as fluorescence). Diamonds fluoresce in both long- and short-wave UV light. The fluorescence is usually greater in long-wave light, and diamond may appear blue, green, yellow, or occasionally red. Fluorescence is generally weak, however, and it may not be readily apparent to the naked eye. In some cases, light emission is still visible for a brief interval after the UV light source is turned off (known as phosphorescence). Some diamonds may also show brilliant phosphorescence when rubbed or exposed to the electric charge in a vacuum tube, or when exposed to UV light (Dana and Ford 1951).

At room temperature, diamond is four times as thermally conductive as copper, even though it is not electrically conductive. Because of the ability to conduct heat, diamond has a tendency to feel cool to the lips when touched, since the gemstone conducts heat away from the lips. This is why diamonds have been referred to as *ice*. Gem testers (about the size of a pen) are designed to identify the unique thermal conductivity of diamond and distinguish it from other gems and imitations.

Diamonds are hydrophobic (nonwetable). Even though diamond is 3.5 times heavier than water, it can be induced to float on water. Because it is hydrophobic, diamond will attract grease, thus providing an efficient method for extracting diamond from ore concentrates (i.e., grease table).

Diamonds are unaffected by heat except at high temperatures. When heated in oxygen, diamond will burn to carbon dioxide (CO₂). Without oxygen, diamond will transform to graphite at much higher temperatures (1,900°C [3,450°F]). Diamonds are unaffected by acids.

ORIGIN AND OCCURRENCE

There are literally thousands of known kimberlites and many hundreds of lamproites and lamprophyres, but only a handful contain commercial amounts of diamond. One estimate made many years ago suggested that less than 1% of all kimberlites are commercially mineralized (Lampietti and Sutherland 1978). Although many hundreds of new discoveries have been made since that paper was published, this statistic remains essentially valid.

Diamondiferous kimberlites and lamproites are essentially restricted to cratons and cratonized terrains. These include stable Archean cratonic cores (known as Archons) as well as cratonized Proterozoic margins (referred to as Protons) (Figure 1). Some unconventional diamondiferous host rocks have also been identified in cratons and outside cratonic terrains within tectonically active regions along the margins of cratons. Because high ore grades have been detected in some of these, unconventional commercial host rocks are anticipated to be found in the future (Erlach and Hausel 2002). Current diamond exploration programs are designed to search for conventional host rocks (i.e., kimberlite and lamproite) or for placers presumably derived from these.

Most diamonds are considered xenocrysts that separated from disaggregated mantle peridotite and eclogite during transportation to the earth's surface in kimberlitic, lamproitic, and some lamprophyric magmas. Kimberlites, lamproites, and lamprophyres tend to occur in clusters of a few to more than 100 occurrences. Structural control is thought to be important in the emplacement of these, and several structural orientations are often recognized within each district.

Kimberlite

The majority of diamond mines are developed in kimberlite such as the Wesselton, DeBeers, Kimberley, Dutoitspan, and Ekati, or in

Adapted from Levinson, Gurney, and Kirkley 1992.

Figure 1. The North American craton showing regions of favorability for conventional diamondiferous host rocks. Major Archean provinces are in all capital letters.

placers, particularly beach placers along the west coast of Africa. Lampietti and Sutherland (1978) reported that only about 10% of the known kimberlites were mineralized with diamond. This statistic may no longer be valid in that as many as 50% of kimberlites found in Canada and Wyoming in recent years, and possibly as many as 90% in Colorado, have yielded diamond. Even so, only a very small portion is commercially mineralized. When economic, kimberlites may contain hundreds of millions to billions of dollars worth of stones; thus kimberlites should be a priority target in any exploration program.

Kimberlites are essentially carbonated alkali peridotites that exsolve CO₂ during ascent to the surface from the earth's upper mantle, resulting in diatremes with considerable brecciation and dissolution-rounded xenoliths and cognate nodules. The diatremes appear as subvertical to vertical pipes that taper down at depth, forming steeply inclined cylindrical bodies. The average angle of inclination of the walls of various pipes in the Kimberley region of South Africa (Wesselton, DeBeers, Kimberley, and Dutoitspan) is 82° to 85°. Ideally, the pipes have rounded to ellipsoidal horizontal cross-sections filled with kimberlitic tuff or tuff-breccia. Many continue from the surface to depths of 2 to 2.4 km, where they pinch down to narrow root zones emanating from a feeder dike.

The Kimberley pipe, which was mined out by 1915 (about 20 years after discovery), contracted sharply at depth. At the lowest level of mining (1,056 m), it was no longer pipe shaped but rather had the appearance of three intersecting dikes (Kennedy and Nordlie 1968). Combined with the estimated 1,600 m of erosion since the time of emplacement, the depth to the original point of expansion was probably 2.4 km.

Figure 2. Exposed contact of a Schaffer diamondiferous kimberlite, Wyoming, showing the knife sharp contact between the kimberlite (left) and granite (right), explained by adiabatic cooling of the kimberlite magma during eruption

Kimberlitic magmas are interpreted to originate from depths as great as 200 km and travel to the earth's surface in a matter of hours (O'Hara, Richardson, and Wilson 1971). The magma is thought to rise rapidly, possibly 10 to 30 km/hr in order to transport high-density ultramafic xenoliths. Within the last few kilometers of the surface, emplacement rates are thought to increase dramatically to several hundred kilometers per hour. Such velocities could bring diamonds from the mantle to the surface in less than a day. McGretchin (1968) estimated that the speed of the fluidized material near the surface increased to as much as 400 m/sec, or about the speed of sound (Mach 1 or 331 m/sec). Some estimates have even suggested kimberlite emplacement at the earth's surface may have achieved velocities exceeding Mach 3 (Hughes 1982).

The temperature of the magma at the point of eruption is relatively cool (Figure 2). Watson (1967) indicated a magma temperature of less than 600°C (1,110°F) on the basis of the coking effects on coal intruded by kimberlite. A low temperature of emplacement is also supported by the absence of any visible thermal effects on country rock adjacent to most kimberlite contacts. Davidson (1967) suggested the temperature of emplacement may have been as low as 200°C based on the retention of argon. Hughes (1982) pointed out that the near-surface temperatures of the gas-charged kimberlite melt may be as low as 0°C (32°F) because of the adiabatic expansion of CO₂ gas as kimberlite erupts at the surface.

Kimberlites typically transport xenoliths and xenocrysts to the surface. Many of these are derived from mantle depths and some form a distinct suite of minerals that are referred to as kimberlitic indicator minerals. The traditional indicator minerals used to explore for kimberlite include pyrope garnet, chromian diopside, chromian enstatite, picroilmenite, chromite, and diamond.

Lamproite

Serious interest in lamproite intensified following the discovery of a world-class diamond deposit in olivine lamproite in 1979 in the Kimberley region at Argyle, Western Australia. The discovery led to the recognition of other diamondiferous lamproites in Australia,

Brazil, China, Gabon, Zambia, Ivory Coast, India, Russia, and the United States.

Scott-Smith (1996) subdivides lamproites into two general groups: phlogopite-leucite lamproites (~60% SiO₂ [silicon dioxide]) and olivine lamproites (>20% MgO [magnesium oxide], 35% to 45% SiO₂, and 7% K₂O [potassium oxide]) with abundant serpentine pseudomorphs after olivine. Instead of pipes with steep walls that slowly diminish in diameter with increasing depth, lamproites are characterized by "champagne-glass" vents filled by tuffaceous rocks, often with massive volcanic rocks in the core.

In some cases, lamproites appear to have formed in the diamond stability field (Nixon 1995). A qualitative correlation between diamond and olivine in lamproite is confirmed in both the Ellendale, Australia, and Kapamba, Zambia, provinces in which diamond grades are consistently higher in olivine lamproites than leucite lamproites. When found, diamonds occur primarily in pyroclastic rocks; the magmatic phases are notoriously diamond poor, owing to the high temperatures sustained in the flows during eruption, which are antipathetic to diamond preservation; that is, the diamonds will burn (Scott-Smith 1986).

Where vents flare out, a potential for substantial tonnages exists in larger craters. At Argyle, Western Australia, past reserve estimates of 94 Mt of ore at an average grade of 750 carats/100 t led to its classification as a world-class deposit. Some of the richer portions of this deposit yielded grades as high as 2,000 carats/100 t. Large numbers of the Argyle diamonds, however, are graphitized and partially resorbed; more than 60% are irregular in shape and include macles, polycrystalline forms, and rounded dodecahedrons. The largest Argyle diamond weighed 42.6 carats; the overall size of diamonds is quite small (average <0.1 carat). Nearly 80% are brown, and the remaining stones are dominantly yellow or colorless. Rare but economically important pink to red diamonds bring Argyle fame (Shigley, Chapman, and Ellison 2001).

Many lamproitic diamonds are relatively small and include common fancy yellow to brown stones. For example, macro diamonds (>1 mm) from the Ellendale field in Western Australia are dominantly yellow dodecahedra, and many micro diamonds are colorless or pale-brown, frosted, step-layered octahedral (Shigley, Chapman, and Ellison 2001).

Placers

Because of a relatively high specific gravity (3.5) and extreme hardness, diamonds are often found in secondary stream or marine placers with other minerals of relatively high specific gravity such as magnetite, spinel, ilmenite, rutile, garnet, and gold. Some of the more productive deposits include stream and marine placers where a large percentage of diamonds are gem quality, owing to fracturing and disaggregation of imperfect industrial diamonds during stream transport. Considerable numbers of diamonds have been mined from stream sediments along the Orange River basin in southern Africa and continuing in beach sands downcurrent from the mouth of the Orange River along the Atlantic coast. Historically, there have been many reports of gold prospectors finding diamonds while searching for placer gold. Examples include California, Colorado, Georgia, North Carolina, and Wyoming in the United States, and New South Wales in Australia (Hausel 1998).

Placer diamond deposits formed throughout geological history as is evident by diamonds in ancient Proterozoic paleoplacers in the Witwatersrand metaconglomerates of South Africa and the Snowy Range Group in Wyoming, United States, as well as modern placers along the Atlantic coast of Africa and Smoke Creek near the Argyle mine, Australia.

DISTRIBUTION AND PRODUCTION

Diamond Production

Diamonds are mined from at least 20 countries, and the leading producers of natural diamond are Australia, Botswana, Canada, South Africa, Russia, and Zaire. The World Diamond Council estimated that natural diamond production in 1999 was more than 111 million carats, valued at US\$7.4 billion. In 2000, diamond production was estimated at more than 110 million carats, valued at US\$7.9 billion. In 2001, the U.S. Geological Survey (USGS) estimated that 119 million carats were mined, with an estimated value of US\$7.3 billion, and in 2003, diamond production estimates stood at 132 million carats (Olson 2003). The *Northern Miner* (Anon. 2005) reported that rough diamond sales in 2003 for the Diamond Trading Company (DeBeers marketing arm) were \$5.52 billion.

Canada ranked sixth in diamond production during the same period, but in the second quarter of 2004, it surpassed South Africa to become the third largest diamond producer (based on value). This is one of the great exploration success stories of the twentieth century because before 1998, Canada did not have a diamond industry (Krajick 2001).

Industrial diamonds have considerably less value than gem diamond, and much of industrial production is now synthetic. In 2001, nearly 70% of the total natural and synthetic industrial diamond production came from Ireland, Russia, and the United States: 92% was synthetic (Olson 2001). According to the USGS, world production of natural industrial diamond totaled 48 million carats in 2001 and 48.9 million carats in 2002. More than one third of the world's natural diamond production was classified as industrial. This represented only a very small percentage (~1%), however, of the total monetary value of natural diamond production. Australia led the market in recovery of natural industrial diamonds and has averaged 22.1 million carats per year; however, declining reserves at the Argyle mine resulted in Australian industrial diamond production of only 13.1 million carats in 2001 and in 2002 (Olson 2003).

The World Diamond Council reported that the United States was the largest producer of synthetic industrial diamonds, with 125 million carats manufactured in 1999. The USGS reported that domestic synthetic industrial diamond production for 2002 was 310 million carats. The total industrial output worldwide was estimated to be in excess of 800 million carats in 2001, valued at more than US\$600 million (Olson 2001). Domestic synthetic diamonds were produced by two companies: GE Superabrasives in Ohio and Mypodiamond Inc. in New Jersey.

Natural diamond production was dominated by southern African countries with a significant contribution by Russia and Australia. Nearly all of the Australian diamond production was from the Argyle mine, which accounted for more than 20% of world's diamonds. The relatively low quality of the Argyle diamonds, however, rendered the production to be less valuable than some smaller operations elsewhere.

Diamond Distribution

Although there are hundreds of known diamond occurrences around the world, commercial diamond deposits are rare. In the richest, diamond occurs in concentrations of much less than 1 ppm (Lampietti and Sutherland 1978). The few commercial diamond deposits are hosted by kimberlite, lamproite, and placers derived from these host rocks. These are all associated with Archean cratons and cratonized Proterozoic belts. The discovery of several unconventional host rocks in recent years, though, some with very high ore grades, suggests that other rock types and geological environments will become diamond targets in the future (Hausel 1996; Erlich and Hausel

Table 1. Diamond production of major mines in 2001

Country	Carats, ×1000	Amount, kt	US\$/carat	Value, US\$ million

Adapted from *Mining Journal* 2002.

The world's natural diamonds are produced from a small group of deposits, which typically have operating lives of 20 to 30 years. A notable exception is the Premier mine (South Africa), which potentially could operate for more than 100 years (Levinson, Gurney, and Kirkley 1992) (see Table 1).

Africa

The Orange River basin with its many tributaries covers a region with more than 3,000 known barren and diamondiferous kimberlite pipes that include some of the richest pipes in the world. The principal diamond-producing countries in Africa are Angola, Botswana, the Central African Republic, the Democratic Republic of Congo (formerly Zaire), Ghana, Guinea, Namibia, Sierra Leone, South Africa, and Zimbabwe. In total, Africa accounts for nearly 50% of the world's diamond production.

Angola. Angola produces 2 million carats of high-quality diamonds annually derived primarily from alluvial sources. Nearly all diamond production is derived from alluvial sources in the Andrada and Lucapara areas of northeastern Luanda Norte and the Cuango River. Only minor amounts are mined from colluvial and eluvial deposits overlying kimberlite at the Camafuca–Camazomba intrusive along the Chicapa River near Calonda. Other kimberlites have been identified in Angola (Janse 1995).

Atlantic Coast. Erosion of diamond pipes and dikes in the Orange River basin resulted in the concentration of millions of diamonds in the basin and along the Atlantic Ocean shoreline. Stream sediments in the basin and beach sands along the west coast of Africa extending from Port Nolloth, Namaqualand, to Luderitz, Namibia, contain placer diamonds. The powerful energy generated by the wave action along this coast has destroyed or broken large numbers of poor-quality stones while gemstones remain intact.

Botswana. DeBeers discovered three world-class kimberlite pipes (Orapa, Letlhakane, and Jwaneng) in Botswana between 1967 and 1973. The Orapa pipe was found in 1967 and production began in 1972. It is the second largest producer of diamonds in the world and yielded more than 13 million carats in 2001 (Table 1). The Jwaneng pipe was discovered in 1973 under the sands of the Kalahari Desert, and mining began on the property in 1982. It has been the third most productive diamond mine by weight and first by value. Two smaller pipes known as the Letlhakane 1 and 2 were discovered in 1968.

Botswana's diamond reserves are immense. Total production in 2001 was a record 26.3 million carats, compared to 21.26 million carats in 1999 and 19.8 million carats in 1998. Output from the mines was 13 million, 1 million, and 12 million carats from Orapa, Letlhakane, and Jwaneng, respectively (Table 1). A fourth mine, Tswapong, produced 10,100 carats in 1999. An application for a fifth mine at Gope in the Central Kgale Game Reserve was reviewed in 1999, and Debswana Diamond Company Ltd. (formed by the Botswana government and South Africa's DeBeers in equal partnership) applied for a license beginning in 2001 to mine diamonds from four small kimberlite pipes known as the B/K pipes near the Orapa mine.

Central African Republic. Diamonds from the Central African Republic are mined from alluvium. Diamondiferous alluvium has been found near Briatouche in the central area of the country; Carnot-Berberati in the southwest; and the Mouka Ouadda plateau in the northeastern portion of the Central African Republic. To date, the source rocks for the diamonds have not been identified. Production amounts to about 500,000 carats per year (Janse 1995).

Democratic Republic of Congo. Formerly known as Zaire, the Democratic Republic of Congo accounts for about 18% of the world production and, in recent years, has been the second largest producer by weight, next to Australia. Only 6% of the Congo diamonds, however, are gem quality with another 40% near-gem, resulting in the Congo being the fourth-ranked producer based on value. According to the American Museum of Natural History Web site (undated), the Mbuji-Mayi mine in the Congo has been a prolific source for diamonds with recent annual production of about 5 million carats.

Ghana. Most diamonds in Ghana (formerly known as the Gold Coast) have been mined from two placers known as the Akwatia and Birim concessions located north west of the capital city of Accra. Annual production peaked at 2,283,000 carats in 1975 and has since declined. About 10% of country's output is classified as gem quality, and most of the remaining stones are micro-diamonds (<2 mm) (Janse 1996). Recoverable resources are estimated to range between 20 and 50 million carats and Ghana's estimated annual production could well exceed 1.3 million carats (Miller 1995). The Akwatia deposits are nearly depleted, but large new resources have been identified at the Birim River deposits. One altered meta-lamproite was found that is thought to represent a primary source for diamonds.

Guinea. Most Guinean diamonds are mined from exceptionally rich gravel placers. Some of the gravel was traced to the Banankoro kimberlite swarms in eastern Guinea, which consists of small uneconomic dikes and pipes. Rich placers mined downstream from the kimberlite swarms were part of the Aredor placer mine (closed in 1993), and produced a number of large diamonds including several that weighed more than 100 carats; the largest was the Guinean Star, weighing 255.6 carats (Janse 1995).

Ivory Coast. Also known as Côte d'Ivoire, Ivory Coast produces a small number of diamonds annually from alluvial deposits and dikes in the Seguela area in the western portion of the country. Alluvial deposits in the Toritya field in central Ivory Coast also pro-

duce a limited number. The source of many diamonds for the Seguela placers is the Toubabouko olivine lamproite dike. Another dike, the Bobi lamproite, has yielded about 400,000 carats from the rock and overlying eluvial deposits (Mitchell and Bergman 1991; Janse 1996).

Lesotho. Several kimberlites were found in Lesotho (formerly Basutoland) but production is limited. Two pipes, the Kao and the Letseng-la-Terai kimberlites, are apparently low grade. The Letseng pipe, however, operated as a commercial mine from 1977 to 1982 and produced some large stones, including a pale-brown 601-carat diamond (Janse 1995).

Liberia. Almost all Liberian diamond production (45% of which is gem quality) comes from small alluvial diggings around Gbapa.

Mali. Alluvial diamonds and kimberlite pipes occur near Kenieba in western Mali, but no commercial diamond deposits have been identified (Janse 1996).

Namibia. Formerly known as South West Africa, Namibia is a source for small high-quality diamonds from placers and alluvium. Essentially all of Namibia's production is derived from alluvial, and coastal and submarine terrace deposits in the Namaqualand coastal region, which includes the coastal region from Luderitz to Bogenfels.

Submerged terrace deposits are mined to depths of 100 m along the coast. These are thought to extend 100 km from shore along the continental shelf (Janse 1995). The Elizabeth Bay deposit along the coast 30 km south of Luderitz began production in 1991 and has yielded many very high-quality small diamonds. The deposit was reported to host 38 Mt of ore averaging 0.066 carats/t. The Auchas mine, located on the north bank of the Orange River 45 km inland, was reported to contain 12.3 Mt averaging 0.036 carats/t. Kimberlites in Namibia occur in five different fields; all have proven to be barren (Janse 1995).

Sierra Leone. Diamonds in Sierra Leone are found in stream and river placers, and in terraces, off-shore terraces, and also in a few kimberlites. Many placers have been depleted, although large high-grade zones are still mined. Kimberlite dikes and two small pipes were found on the Tongo deposit. The dikes were relatively rich, but their narrow width made them unfavorable for mining. The small Koidu pipe (0.4 ha) has an ore grade reported at 1.0 carat/t and is reported to host a very high occurrence (60%) of gem-quality stones. Sierra Leone is known for its relatively large, high-quality placer gemstones, and has produced some very attractive stones including the Woyie River diamond, which weighs 770 carats.

South Africa. Diamonds were initially reported in South Africa in the 1860s, and between 1870 and 1871, a great diamond rush occurred along the Orange River, resulting in discovery of several deposits (Wagner 1914). South Africa is the fifth largest producer of diamonds (by value) with annual production of 8 to 10 million carats. In 2001, the South African mines produced 10.65 million carats. The region has produced more than 500 million carats since the 1860s. A high percentage of these have been gem and near-gem, and South African mines have produced some of the largest diamonds found in history.

The diamonds occur in kimberlite pipes and dikes and in associated alluvial placers. The largest pipe in South Africa is the 54-ha Premier. The Premier mine has been the source of some of the world's largest diamonds, including the Cullinan, Premier Rose, Niarchos, Centenary, and Golden Jubilee. The largest diamond ever found, the fist-size (3,106 carats) Cullinan, was recovered from the Premier.

The Finsch mine covers 17.9 ha and lies 160 km northwest of Kimberley. It is one of De Beers' seven South African operations.

Discovered in 1961, the deposit was initially developed by open pit. Since 1991, underground mine operations continued beneath the abandoned pit. Production from the mine in 2001 was 2.46 million carats from 4.8 Mt of ore (51.7 carats/100 t).

Diamond-bearing gravels were discovered as early as 1903, close to the Limpopo River, 35 km northeast of the present location of the Venetia mine in South Africa. In 1969, DeBeers launched a reconnaissance sampling program to locate the source of the alluvial deposits, and kimberlite pipes were discovered upstream in 1980. Mine construction began in 1990, and the Venetia mine opened in 1992, with full production in 1993. This mine represents one of DeBeers' single largest investments in South Africa. Situated 80 km from Messina in the Northern Province, the property required a capital investment of \$400 million. The mine produced 4.98 million carats from 4.6 Mt of ore in 2001 (108 carats/100 t).

There are 12 kimberlites in the Venetia cluster. Of the 11 pipes and 1 dike, only two kimberlites, K1 and K2, are currently being mined. Some of the pipes were formed by multiple intrusive events, resulting in a variety of kimberlite facies. The kimberlites are clustered over approximately 3 km, and the total surface area of kimberlite is 28 ha. Venetia is being mined by conventional open pit. Surface mining is expected to continue for 20 years with the targeted pit depth of 400 m.

Swaziland. One small commercial operation is reported in Swaziland. Janse (1995) describes an alluvial deposit referred to as the Hlane occurring downstream from the small (2.8 ha) Dokolwayo kimberlite pipe. The placer has produced about 50,000 carats/year since 1983.

Tanzania. Diamonds were initially found in alluvial deposits and later in eluvium on the Mabuki kimberlite 60 km south of Lake Victoria in northern Tanzania. In 1940 another diamondiferous kimberlite of significance was found 140 km south of Lake Victoria by an independent Canadian prospector, John Williamson, who apparently rode a bicycle in his search for diamonds. This pipe, the largest economic kimberlite ever found, is known as the Mwadui pipe. The Mwadui is 1,500 m in diameter, covering 146 ha of surface area. The pipe produced some fine pink stones and averaged more than 500,000 carats annually in the 1960s, with declining production in recent years. DeBeers later discovered hundreds of other kimberlites in this region; none have been productive (Janse 1996).

Zimbabwe. Formerly known as Rhodesia, Zimbabwe has produced minor amounts of diamonds from alluvium. The first kimberlite found in southern Zimbabwe—named the Colossus pipe—was discovered near Lochard in 1907. The pipe was reported to be 1 km in diameter (Wagner 1971). Janse (1995), however, indicated the kimberlite to be considerably smaller (900 by 150 m) and not viable. Other kimberlites were found but all proved to be unprofitable with the exception of the River Ranch kimberlite, discovered in 1975. A mine was officially opened there in 1995, but production was minimal and operations ceased in 1998 (Janse 1995).

Australia

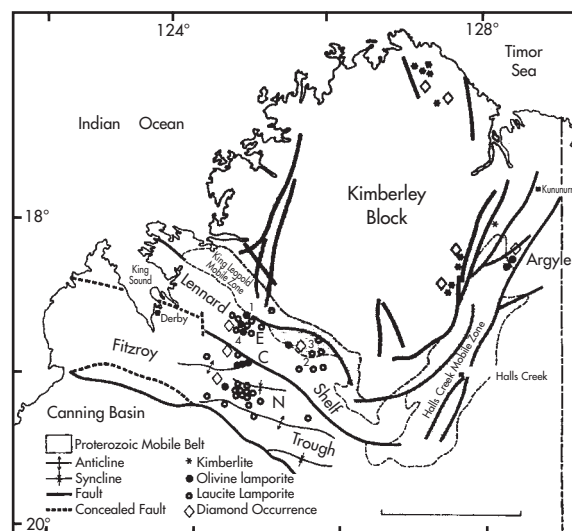

New South Wales. Alluvial diamonds were initially reported in New South Wales (NSW) in 1861, and were later found in Queensland (1887), in South Australia (1894), and in Tasmania (1899). From 1884 to 1922, 167,548 diamonds (with stones weighing as much as 8 carats) were recovered from alluvium in the Copeton field, NSW.

The diamonds were found in gravel buried by Tertiary basalt in an active tectonic environment similar to that of the Urals in Russia, the west coast of the United States, and some Archean greenstone terrains in Canada (Erlich and Hausel 2002; Ayer and Wyman 2003; Kaminsky, Sablukov, and Sablukova 2003). It is

Figure 4. The Kimberley block, Western Australia, showing locations of kimberlites, lamproites, diamonds, the Ellendale field (E), Calwinyardah field (C), and Noonkanbah field (N)

thought that the diamonds were derived from phreatomagmatic volcanoclastics and tuffs associated with lamprophyre pipes (Atkinson and Smith 1995). Diamonds in such geological terrains provide signatures, suggesting derivation from a relatively shallow mantle (<80 km) (Ayer and Wyman 2003).

Northern Territories. Decades after the diamond discoveries in NSW, Ashton Exploration discovered diamonds in 1976 near Mt. Percy, West Kimberley, by following a trail of kimberlitic indicator minerals. The mineral trail led to diamondiferous lamproite in the Ellendale field (Tertiary). In August 1979, diamonds were found in Smoke Creek, more than 350 km to the northeast. In October 1979, the 1.2-billion-year-old (Ga) Argyle lamproite was discovered (Atkinson and Smith 1995) (Figure 3). Both lamproite fields are located within Proterozoic mobile belts cratonized about 1.8 Ga and were tectonically active until the Devonian or later (Jacques et al. 1982, 1983; Atkinson, Smith, and Boxer 1984) (Figure 4).

Currently, about 450 lamproites, kimberlites, and lamprophyres have been identified in Australia, of which more than 180 are diamondiferous. Some of the recently discovered kimberlites yielded minor to significant diamond grades (Berryman et al. 1999).

Production began in the mid-1980s at the Argyle mine, and Australia became a leading diamond producer. At full production, the mine yielded more than 30% of the world's annual production. Further development of the open pit continued into 2001, and the current operator (Rio Tinto) reported plans to expand operations underground.

Diamonds were recovered from the Normandy Bow River placer mine in the lower reaches of Limestone Creek, 20 km northeast of the Argyle. This deposit was discovered in the early 1980s and mined by Poseidon/Freeport and Normandy from 1988 until late 1995 (Biggs and Garlick 1987). The plant was inactive at the end of late 1995, after nearly 7 million carats were produced from 24 Mt of gravel.

Kimberley Diamond Company acquired the Ellendale leases previously held by Argyle Diamond Mines. Initial bulk sampling results from Ellendale 4 and 9 revealed higher ore grades near the surface. The company reported the Ellendale 4 resource at more than 2 million carats to a depth of 140 m (23 Mt at 0.088 carats/t), which included a higher-grade zone (444,000 t at 0.261 carats/t) to a depth of 3 m. The near-surface enrichment zone was part of the mining target for 2002. Primary diamond resources of Ellendale 4 and 9 were estimated at more than 2.6 million carats.

For the first 3 years of operation, 2.2 Mt of ore was expected to be mined from the top 3 m of enriched material on both Ellendale 4 and 9. The ore was estimated to average 0.15 carat/t. The company also reported the discovery of 11 previously unknown lamproite pipes in the area (Shigley, Chapman, and Ellison 2001).

The Merlin mine, which was developed on a group of 12 diamondiferous kimberlites in northern Australia, yielded the country's largest diamond, the 104.73-carat Jungiila Bunajina ("star meteorite dreaming stone") white diamond. Merlin is located 80 km south of Borroloola. After 6 years of production, the mine closed in 2002 because of marginal ore.

Australia's total diamond production in 2001 was 26.2 million carats, a decrease of 0.4 million carats from the previous year. The Argyle mine (26.1 million carats) accounted for nearly all of the Australian production. At one point, Argyle mined nearly 40% of the world's annual diamonds: by the end of 2000, the mine had produced an extraordinary 558 million carats (Shigley, Chapman, and Ellison 2001). The Merlin mine in the Northern Territory produced 55,000 carats, making it the second largest Australian producer in 2001.

Brazil

A diamond rush occurred in Brazil in 1725, and by the end of 1729, several diamond placers had been found in eastern Brazil in the region of Diamantina ("diamond city"). Placers were also found along the Sao Francisco, Parana, Goyas, and other streams in southeastern Brazil.

In 1844, rich diamond placers were found in another region of Brazil—the state of Bahia to the north. During the first 120 years of mining, about 10 million carats were recovered, including some stones weighing more than 100 carats.

The primary source of the diamonds has not been found, and it was initially assumed that a rock referred to as itacolomite (micaeous sandstone) was the source. This assumption was based on the presence of middle Proterozoic diamondiferous conglomerates that have supported some small mining operations in the Diamantina Area.

The large number of diamonds found in placers suggests that major primary diamond deposits will be found in Brazil some day. Since 1967, a systematic exploration program identified more than 300 kimberlite, lamproite, kamafugite, and melilitite intrusives, none of which contain economic amounts of diamond (Bizzi et al. 1994; Meyer et al. 1994). A total of about 55 million carats have been recovered from Brazil, with annual production averaging about 1.2 million carats.

China

Diamond deposits in Liaoning Province in China are associated with kimberlite. More than 100 kimberlites are found in this region, including the Jingangshi Kimberlite, which contains commercial amounts of diamond (Sunagawa 1990). At another locality, the Changma mine in Shandong Province near Mengyin, about 500 km southeast of Beijing, is China's largest diamond producer. This deposit was initially mined as an open pit over the past several decades and converted to underground mining in 2002, with an expected life of another 30 years. The Changma deposit consists of two kimberlite diatremes and a dike that all merge at 40 m below the surface. The kimberlite has been drilled to depths of 600 m. Production from the mine during the past 30 years included 1.6 million carats recovered from ore that averaged 1.27 carats/t; the largest diamond was a 119-carat stone. The property has an indicated resource of 1.4 Mt of ore at a grade of 0.92 carats/t with an inferred resource of 1.5 Mt of 0.63 carats/t. The Changma property includes nine diamondiferous kimberlites with a total measured and indicated resource of 9.7 Mt at an average grade of 0.055 carats/t (Beales 2004).

India

Diamonds were reported in the Golconda region of India from medieval time to the nineteenth century. Golconda was actually the marketplace, and the source of the diamonds were placers in the Penner, Karnool, Godvari, and Makhnadi rivers in the Krishna Valley, and possibly in the Panna diamond field to the north in south-central India (Mathur 1982). Many of the better diamonds ended up in the royal treasuries of sultans and shahs of India and Persia. Total production is estimated at about 12 million carats (Milashev 1989).

The majority of the diamonds was found in placer deposits (Sakuntala and Brahman 1984), although diamonds were also found in the Majhagawan lamproite as early as 1827. After kimberlite was described in South Africa in 1877, intensive exploration in the ancient diamond-producing areas of India resulted in the discovery of what was thought to be kimberlite in areas adjacent to many placers (e.g., Majhagawan and Hinota near the Panna placer district, and the Wajakurnur and other intrusives in the Anantpur District). Years later, petrographic studies of some Indian kimberlites confirmed that many were actually olivine lamproite (e.g., Majhagawan and Chelima) (Scott-Smith 1989; Middlemost and Paul 1984; Rock et al. 1992). Diamonds recovered from the pipes are mostly transparent and flawless, with dominantly octahedral and dodecahedral habits. About 40% are gem quality (ore grade ~0.01 carats/t).

Mitchell and Bergman (1991) indicated that there are several other lamproites, kimberlites, and peridotites in this region, and Rock and others (1992) also reported several olivine lamprophyres and minettes of potential economic interest in eastern India. Known kimberlites in India are primarily Proterozoic in age and include diamondiferous kimberlites in the Wajrakarur field in the Andhra Pradesh of the southern kimberlite province and kimberlites in the Raipur field in southeastern Madhya Pradesh in the central province (Middlemost and Paul 1984).

Many of the Indian deposits were depleted by the nineteenth century and new deposits were discovered in the mid-twentieth century, including placers in the Junkel region and Koel Valley, and in the Simla region near the Himalayas (which were originally described in Sanskrit texts). Total historical production is estimated to be between 14 and 21 million carats. Currently, about 20,000 carats are produced each year.

North America

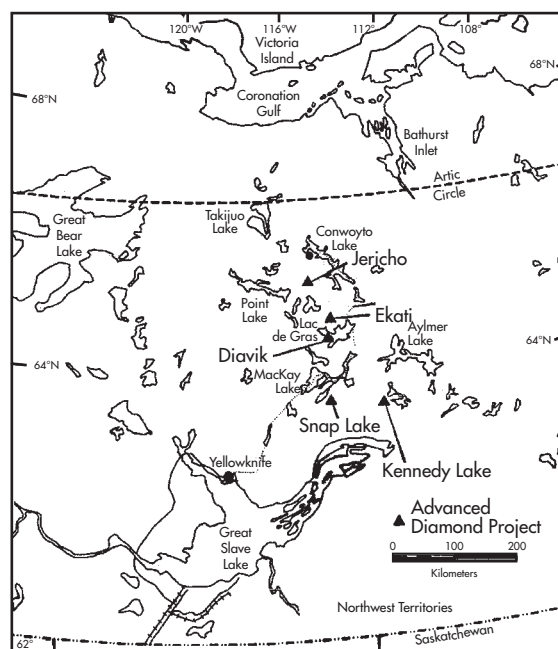

There is little doubt that Canada, which has become a major diamond producer, will remain in the forefront of diamond production and exploration for decades to come. Recent exploration in Canada has resulted in the discovery of more than 500 kimberlites (including some unconventional host rocks), of which nearly half are diamondiferous (Kjarsgaard and Levinson 2002). Some of the unconventional host rocks include lamprophyre (including minette) and actinolite schist at Wawa, Canada, that is interpreted to represent metamorphosed komatiite.

The North American craton is the largest in the world. The cratonic basement rocks of Canada continue south into the United States and underlie large parts of Montana–Wyoming and the Great Lakes region. Exploration in the United States, however, has been relatively minimal. Even so, more than 100 kimberlites, lamproites, and lamprophyres have been identified in the southern extension of the North American craton in Colorado, Wyoming, and Montana. Approximately half of the kimberlites found in Colorado and Wyoming are diamondiferous; only one in Montana has yielded diamonds to date. One mine was developed along the edge of the Wyoming craton in 1995–1996. The Kelsey Lake mine in the Colorado–Wyoming State Line District south of Laramie, Wyoming, contained low-grade ore (about 0.05 carats/t) and yielded some high-quality diamonds weighing as much as 28.3 carats (Coopersmith, Mitchell, and Hausel 2003). Mine operations ended because of legal problems.

The presence of several hundred kimberlitic indicator mineral anomalies, several diamonds, and some geophysical and remote sensing anomalies support the concept that the Wyoming craton has been intruded by a major swarm of kimberlitic and related intrusives, most of which remain undiscovered. Because a large part of the Wyoming craton remains unexplored for diamonds, additional discoveries are expected. In the Great Lakes region, a group of about 30 kimberlites are reported in the Michigan–Illinois Area (eight of which contain trace amounts of diamond) (Hausel 1998).

One of the great exploration success stories of the twentieth century was the discovery of diamonds in the Northwest Territories of Canada, which sparked the largest claim-staking rush in history (Krajick 2001). A group of diamondiferous kimberlites were found nearly 300 km northeast of Yellowknife under a group of shallow lakes in the Lac de Gras region. Within a few years following the discovery, BHP commissioned Canada's first diamond mine in late 1998 (Figure 5). This mine, known as Ekati, is a world-class mine. The mine property includes a group of 121 kimberlite intrusives, and to date, commercial mineralization has been identified and reserves established for the Fox, Leslie, Misery, Koala, Koala North, Panda, Beartooth, Sable, and Pigeon kimberlites on the Ekati property; the other kimberlites are being evaluated for reserves. The mine is anticipated to have a minimum life of at least 25 years.

In 2001, Ekati produced 3.7 million carats, totaling about 6% of the world's diamond value. In 2003, production increased to 6.96 million carats (Anon. 2004). The open-pit operation on the Panda kimberlite reached its maximum economic depth in 2003, 5 years after mining was initiated. The declining production from the Panda open pit, however, was replaced by production from the nearby Misery and Koala open pits. Evaluation showed that the

Figure 5. Important diamond localities in Canada

Panda kimberlite mine life could be extended using underground mining techniques; thus, the remaining kimberlite is being developed using sublevel retreat mining. Underground mining was previously initiated at the adjacent Koala North pipe in 2002. The Panda underground mine is expected to produce 4.7 million carats over an operating period of 6 years, with production scheduled to begin in 2005, followed by full production in 2006. The Ekati production for the first quarter of 2004 totaled 1.27 million carats of diamonds, which was a 40% decline from the previous quarter. For the first 9 months of fiscal year 2004, the Ekati mine produced more than 5.3 million carats.

Ore reserves at the Ekati mine are substantial. On June 30, 2003, the Ekati mine reported 47.7 Mt of ore reserves graded at 0.8 carats/t (36.6 million carats of recoverable diamonds) based on a 2-mm cut-off size. Measured, indicated, and inferred kimberlite resources stood at 127.9 Mt of ore containing an estimated 171.2 million carats (Robertson 2004). As exploration continues on the property, these reserves will increase.

A few other commercial properties have been identified in the Northwest Territories, and several other properties are being explored or evaluated for reserves. These include Snap Lake, Diavik, and Jericho.

Production at the Diavik mine began in 2003. The Diavik pipes located in the Lac de Gras region east of Ekati are being mined by Diavik Diamond Mines based at Yellowknife (Figure 5). Diavik Diamond Mines is a subsidiary of London-based Rio Tinto, and the mine is a joint venture between Rio Tinto (60%) and Toronto-based Aber Diamond Mines (40%). Rio Tinto assumed operating responsibility from their subsidiary, Kennecott Canada Exploration. The deposit is estimated to contain 138 million carats of diamond and includes four kimberlites (A154S, A154N, A418, and A21). The A154S kimberlite is one of the richest kimberlites in the world and contains a reserve of 11.7 million carats at an average grade of 5.2 carats/t. The property is anticipated to yield 6 to

8 million carats/year when in full production and has reserves that will sustain the operation for 16 to 22 years. The property lies on a 20-km² island known as East Island, 300 km northeast of Yellowknife. The Diavik kimberlites (55 million years old [Ma]) intruded the Precambrian basement complex (2.5 to 2.7 Ga).

The Snap Lake mine is located in a kimberlite dike about 100 km south-southeast of Ekati and 220 km northeast of Yellowknife. Snap Lake will be DeBeers' first mine developed outside of southern Africa and is anticipated to begin production in 2006, or possibly as late as 2008. The kimberlite will be mined entirely underground. The kimberlite is estimated to contain 38.8 million carats with an average ore grade of 1.46 carats/t.

Toronto-based Tahera Diamond Corporation is the operator of the Jericho project, located about 170 km north of Ekati near Echo Bay's Lupin gold mine. This property includes six diamondiferous kimberlites within the Nunavut Territory. When placed into production, the property will produce about 6 million carats over a mine life of 8 years. Reserves of 2.6 Mt of ore averaging 1.2 carats/t have been established. The mine is expected to begin development in 2004 and production is scheduled for 2005 (Anon. 2004).

Another project of DeBeers Canada—the Victor Project—lies in the James Bay Lowlands. Victor is one of 18 kimberlite pipes discovered on the property, 16 of which are diamondiferous. The Victor kimberlite has a surface area of 15 ha and consists of two pipes, known as the Victor Main pipe and Victor Southwest pipe, that coalesce at the surface. The Victor kimberlite is a complex pipe consisting of pyroclastic crater and hypabyssal facies kimberlite and has highly variable diamond grades. If a decision is made to put the property in production, the open-pit mine will have a life of 12 years and total project life of 17 years. The proposed mine would be supported by a processing plant designed to process 2.5 Mtpy.

DeBeers is also involved in the Kennady (Gahcho Kue) Lake project, about 100 km east of Snap Lake near Ft. Defiance and southeast of Ekati. Kennady Lake is under exploration by a joint venture between Mountain Lake Resources and DeBeers. The property includes the 5034, Hearne, and Tuzo kimberlites. Initial sampling of the 5034 and Hearne pipes yielded an average ore grade of 1.67 carats/t. If this project receives a go-ahead, it is expected that permitting will require 2 to 3 years followed by another 3 years of mine development (Anon. 2004).

Since the 1990s, many other deposits have been found in Canada in the Northwest Territories, Nunavut, Alberta, Ontario, Quebec, and Saskatchewan (Olson 2001).

According to *Engineering and Mining Journal* (Anon. 2004), Canada is currently supplying about 15% of the world's diamonds and is expected to show dramatic increases in the future. In 2002, the Canadian diamond industry produced nearly 5 million carats. In 2003, production increased to 11.2 million carats, and it is estimated that essentially 50% of the world diamond exploration funding is focused on Canada.

Russia

The official discovery of kimberlite in Russia occurred in 1954 at what later became known as the Mir pipe (Erlich and Hausel 2002). In 1957, development began on placers associated with the Mir pipe and was followed by open-pit operations in the kimberlite. Years later, operations ceased at a depth of 340 m. The average ore grade was high in the upper mine levels (4.0 carats/t) but decreased near the bottom of the pit (1.50 to 2.0 carats/t). The Mir had high gem to industrial diamond content and was the source of several large gems, including the Star of Yakutia (232 carats) and the Diamond of 26th Party Congress (342.57 carats). Annual output from the mine was 6.0 million carats (Miller 1995).

The Udachnaya pipe was found in 1955, and mining began on the associated placers in 1957, followed by open-pit operations in the pipe. Udachnaya has been the most productive diamond mine in Russia with more than 14.4 million carats mined, of which 80% were gems. By 1956, over 500 kimberlites had been discovered in the former U.S.S.R. During the next 30 years, Russia became the third largest producer in the world; nearly all its production came from mines within the northern Siberian platform.

In 1960, the Aikhal pipe was discovered in Yakutia, where mining began in 1962 and ceased sometime between 1981 and 1988, presumably because of overproduction from other sources. Production resumed after 1988, and by 1995 the pit reached a final depth of 240 m. Annual production at the peak of mining was 600,000 carats at an average grade of 1.0 carat/t (Erlich and Hausel 2002).

Another commercial pipe, known as the Sytykanskaya, was discovered in 1955. Open-pit mining began in 1979, and 600,000 carats/year were produced (average grade of 0.60 carat/t). Another commercial diamond mine, the Internatsional'naya pipe, was found in 1969. Mining began in 1971 and the open pit was developed to a depth of 280 m by 1980. Open-pit operations ceased, but plans were made to resume mining underground.

The 23rd Party Congress pipe was discovered in 1959, and mining on this very rich pipe began in 1966. The ore averaged 6.0 carats/t and the open pit reached a depth of 124 m after 15 years of operation. The Jubilee (Yubileinaya) pipe was discovered in 1975. Following the removal of 70 to 100 m of basalt overburden, open-pit mining began. The Jubilee was anticipated to replace production from the declining Udachnaya pipe.

During the 1970s, other diamondiferous kimberlites were discovered within the Russian platform. At about the same time, several kimberlitic pipes were discovered northeast of the city of Arkhangel'sk, which included the Lomonosov diamond deposit. Currently, Russia is the fourth largest producer of diamonds in the world (by weight). The American Museum of Natural History Nature of Diamonds exhibit in New York City reported that the country has produced a total of 332 million carats and currently has an annual production of 10 to 12.5 million carats.

Venezuela

In 1890 and 1901, secondary placer deposits were discovered in Venezuela and Guyana, and near the end of the 1960s, a placer deposit was found on Caroní River in southeastern Venezuela. To mid-1969, 1.3 million carats had been mined; the largest stone weighed 12 carats. In September 1971, near the town of Salvación in the state of Bolívar, another significant placer was discovered. Within a short period, monthly diamond production from the Salvación region reached 50,000 carats, but the source of the diamonds remains unknown.

Other Cratons

Several diamondiferous pipes have been reported in other cratons such as in the Greenland region, and also in Kazakhstan. Kazakhstan also has the added attraction of having some very unusual and very rich unconventional metamorphic diamond deposits—but most of the diamonds are small, low-value industrial micro-diamonds (Erlich and Hausel 2002).

EXPLORATION

Cost figures for annual diamond exploration amounts to tens of millions of dollars. Capitalization costs for the development of the Ekati diamond mine in the Northwest Territories alone were more than US\$800 million. Regional circumstances will dictate which

exploration method will need to be used; however, when an exploration program begins, priority is given to areas of favorability for finding "traditional" diamondiferous host rocks. For example, commercial diamondiferous kimberlites are considered to be restricted to cratonic regions that have been relatively stable for about 1.5 Ga. Janse (1984, 1994) suggested that cratons be separated into areas of favorability known as Archons, Protons, and Tectons. This method for outlining regions of favorability provides an excellent first option priority list.

Archons (Archean basement stabilized more than 2.5 Ga ago) are considered to have high potential for discovery of commercial diamond deposits hosted by kimberlite and possibly lamproite and lamprophyre. Protons (Early to Middle Proterozoic [2.5 to 1.6 Ga] basement terrains) have moderate potential for commercial diamond deposits in kimberlite and high potential for similar deposits in lamproite and possibly lamprophyre. Tectons (Late Proterozoic [1.6 Ga to 600 Ma] basement terrains) are considered to have low potential for commercial diamondiferous host rock. Unconventional diamond deposits (such as high-pressure metamorphic complexes, astroblemes, subduction-related complexes, and divolcaniclastics) may occur in tectonically active terrains, but the methods for exploration for these are not well defined.

Following selection of a favorable terrain, topographic and geological maps, aerial and satellite imagery, and aerial geophysical data are examined. Unusual circular depressions, circular drainage patterns, noteworthy structural trends, and vegetation anomalies are noted. Geophysics is used to search for distinct ("bull's eye") conductors and magnetic anomalies. Geochemical data are examined for chromium (Cr), nickel (Ni), magnesium (Mg), and niobium (Nb) anomalies.

Stream-Sediment Sampling

One of the primary methods used in diamond exploration is a stream-sediment sampling program designed to search for "kimberlitic indicator minerals" (pyrope garnet, chromian diopside, chromian enstatite, picroilmenite, chromian spinel, and of course diamond). Diamond targets are small and can range from diatremes of several hectares to narrow dikes and sills. Diamond-bearing kimberlites and lamproites typically contain abundant soft serpentine with resistant mantle-derived xenocrysts and xenoliths. The serpentine matrix tends to decompose, releasing distinct, mantle-derived, kimberlitic indicator minerals into the surrounding environment. The indicator minerals may be carried downstream for hundreds of meters or several kilometers, depending on the climatic and geomorphic history of the region. Diamonds, however, are thought to be carried considerable distances—in some cases, hundreds of kilometers. The indicator minerals can provide a trail leading back to the source.

In the planning stages of stream-sediment sampling, proposed sample sites are initially marked in prominent drainages on a topographic map using a sample spacing designed to take advantage of the region. In arid regions, sample spacing should take advantage of relatively short transport distances of the indicator minerals. In subarctic to arctic areas (i.e., Canada, Sweden, Russia, etc.), sample density may be considerably lower, owing to the greater transport distance and the logistical difficulties of collecting samples. Anomalous areas are then resampled at a greater sample density.

The usual kimberlitic indicator minerals are rare to nonexistent in lamproite; thus other minerals (zircon, phlogopite, K-rich feldspar, armalcolite, priderite) may be considered that unfortunately have low specific gravity and poor resistance to abrasion, and are potentially difficult to identify. The better indicators for diamondiferous lamproite are diamond and magnesiochromite.

To take advantage of the dispersion of kimberlitic indicator minerals, the size of samples are determined based on the environment. For example, much larger samples are taken where there is a general lack of active streams compared to regions with active drainages. In areas with juvenile streams, samples are often panned on site to recover a few pounds of sample concentrate. Recovered indicator minerals are tested for chemistry using an electron microprobe to identify those that have higher probability of originating from the diamond stability field. The data are plotted on maps to facilitate evaluation.

Geomorphology

Kimberlite and olivine lamproite are often pervasively serpentinized, making outcrops the exception rather than the rule. In many cases, geomorphic expressions of pipes are subtle to unrecognizable. The Kimberley pipe in South Africa was expressed as a slight mound, but nearby pipes (i.e., Wessleton pipe) were expressed as subtle depressions. Others produced subtle modifications of drainage patterns (Mannard 1968). In the subarctic, where glaciation has scoured the landscape, some kimberlites produce noticeable depressions filled by lakes. In the semiarid region of Wyoming and Colorado, a few kimberlites are expressed as slight depressions, but most blend into the surrounding topography and may or may not have a subtle vegetation anomaly.

In the Ellendale field, in Western Australia, serpentinized diamondiferous olivine lamproites lie hidden under a thin layer of soil in a field of well-exposed leucite lamproite volcanoes. The Argyle lamproite and diamondiferous lamproites in the Murfreesboro Area of Arkansas were also hidden by a thin soil cover.

Lineaments

Many kimberlites and lamproites are structurally controlled (Hausel, McCallum, and Woodzick 1979; Hausel, Glahn, and Woodzick 1981; Macnae 1979, 1995; Nixon 1981; Atkinson 1989; Erlich and Hausel 2002). Controlling lineaments and fractures may be indicated by alignment of a cluster of intrusives or by the elongation of a pipe. In Lesotho, South Africa, Dempster and Richard (1973) reported a close association of kimberlite with lineaments: 96% of kimberlites were found along west–northwest trends, and many pipes were located where the west–northwest trends intersected west–southwest fractures.

Lamproites in the Leucite Hills, Wyoming, are found on the flank of the Rock Springs uplift, where distinct east–west fractures lie perpendicular to the axis of the uplift (Hausel, Gregory, and Sutherland 1995). In the West Kimberley Province of Western Australia, some lamproites are spatially associated with the Sandy Creek shear zone, a Proterozoic fault. In the Ellendale field, several lamproites lie near cross faults perpendicular to the Oscar Range trend, even though the intrusions do not appear to be directly related to any known fault. The Argyle lamproite to the east has an elongated morphology suggestive of fault control and intrudes a splay on the Glenhill fault (Jaques, Lewis, and Smith 1986).

Remote Sensing

Kingston (1984) reported that remote-sensing techniques are widely used to search for kimberlite; these include conventional and false color aerial photography, Landsat multispectral scanner satellite data, and airborne multispectral scanning. Multispectral scanning data are used to identify spectral anomalies related to magnesium-rich clays (i.e., montmorillonite), carbonate, and other material with low silica content. Image enhancement techniques (contrast enhancements, ratios, principal components, and clustering) produce images that are optimum for discrimination of kimberlite and

olivine lamproite soils. These and other photo images can be used to search for vegetation and structural anomalies. Airborne multispectral scanning provides higher resolution than Landsat and can also be used to measure reflectance qualities of clay in soil.

Many pipes and dikes possess distinct structural qualities or vegetation anomalies that may allow detection on aerial photographs. Mannard (1968) reported that kimberlites in southern and central Africa were identified on aerial photographs on the basis of vegetation anomalies, circular depressions or mounds, and tonal differences. Low-level aerial photographs (both conventional and false color or infrared) have been used to locate kimberlite in the former U.S.S.R. (Barygin 1962) and in the United States (Hausel, McCallum, and Woodzick 1979; Hausel et al. 2000, 2003).

Geophysical Surveys

Geophysical exploration has been successful in the search for hidden kimberlite and lamproite (Litinskii 1963a, 1963b; Gerrits 1967; Burley and Greenwood 1972; Hausel, McCallum, and Woodzick 1979; Hausel, Glahn, and Woodzick 1981; Paterson and MacFadyen 1984; Woodzick 1980), particularly in districts where kimberlites have previously been discovered. Contrasting geophysical properties are often favorable for distinguishing kimberlite, lamproite, and minette from country rock.

INPUT airborne surveys are effective in identifying both serpentinized and weathered kimberlite, owing to the combination of electromagnetics and magnetics used in the survey. Rock exposures of kimberlite may yield magnetic signatures but are poorly conductive, whereas deeply weathered kimberlites are conductive but poorly magnetic.

Because of the relatively small size of the diamond host rock, close flight-line spacing is necessary. In an airborne INPUT survey over the State Line District, Wyoming, a flight-line spacing of 200 m effectively detected several kimberlites and identified distinct magnetic anomalies interpreted as blind diatremes (Paterson and MacFadyen 1984). An aeromagnetic (200- to 400-m line spacing) survey flown over parts of northeastern Kansas identified several anomalies, some of which were drilled, resulting in the discovery of previously unknown kimberlites (i.e., Baldwin Creek, Tuttle, and Antioch kimberlites) (Berendsen and Weiss 2001). Flight-line spacings of 50 to 100 m were used for INPUT, magnetic, and radiometric surveys in the Ellendale field in Australia (Atkinson 1989; Janke 1983; Jaques, Lewis, and Smith 1986). The olivine lamproites yielded distinct dipolar magnetic anomalies.

In Yakutia Province, Russia, ground magnetic surveys were used where differences between the magnetic susceptibility of kimberlite and the carbonate sedimentary country rock were high. Airborne surveys also successfully detected anomalies as great as 5,000 gammas (Litinskii 1963b). In Mali, West Africa, the magnetic contrast between kimberlite and schist and sandstone country rock resulted in 2,400-gamma anomalies over kimberlite (Gerrits 1967). In Lesotho, anomalies over kimberlite were comparable with those in Yakutia Province (Burley and Greenwood 1972).

Fipke and colleagues (1995) indicated that barren peridotite phases in Arkansas yielded magnetic highs, but the diamondiferous phases were not detected. In northeastern Kansas, Brookins (1970) reported large positive (550 to 5,000 gamma) and negative (0 to -2,800 gamma) anomalies over some kimberlites emplaced in regional sedimentary rocks. The sedimentary rocks had relatively low magnetic susceptibility, making magnetic surveys an effective method for exploration.

Most kimberlites in the Colorado–Wyoming State Line District yielded small complex dipolar anomalies in the range of 25 to 150 gammas, with some isolated anomalies of 250 and 1,000 gam-

mas (Hausel, McCallum, and Woodzick 1979). Blue ground (weathered) kimberlite tends to mask magnetic anomalies. In the Iron Mountain District, where much of the kimberlite is relatively homogeneous, massive hypabyssal-facies kimberlite, only weak to indistinct magnetic anomalies were detected (Hausel et al. 2000).

Magnetite is replaced by hematite during weathering, masking near-surface magnetic affinity. Clay produced during weathering promotes water retention, thus weathered blue ground over kimberlite may produce vegetation anomalies that are susceptible to detection by electrical methods. For example, resistivity surveys in the Colorado–Wyoming State Line District detected apparent resistivity of 25 to 75 ohm-m over weathered kimberlite, compared with 150 to 2,250 ohm-m in the country rock granite (Hausel, McCallum, and Woodzick 1979).

Resistivity of weathered lamproite may be lower than that of country rock, owing to the conductive nature of smectitic clay relative to illite, kaolinite, and other clay minerals (Gerrits 1967; Janke 1983). The Argyle olivine lamproite, however, yielded moderate to strong resistivity anomalies (40 to 100 ohm-m) compared to the surrounding country rock (200 ohm-m) (Drew 1986).

Biogeochemical and Geochemical Surveys

Kimberlite and lamproite are potassic alkalic ultrabasic igneous rocks with elevated barium (Ba), cobalt (Co), Cr, cesium (Cs), phosphorus (P), lead (Pb), rubidium (Rb), strontium (Sr), tantalum (Ta), thorium (Th), uranium (U), vanadium (V), and light rare earth elements (LREE). The elevated Cr, Nb, Ni, and Ta may show up in nearby soils (Jaques 1998), but dispersion of these metals in soils is not extensive. Stream-sediment geochemistry generally is not useful because of efficient dispersion of most metals in streams. In the Colorado–Wyoming State Line District, Cominco American outlined several known kimberlite intrusives on the basis of Cr, Nb, and Ni soil geochemical anomalies. Dispersion patterns were restricted, however, and of little use in exploration in this terrain.

Gregory and Tooms (1969) found that Mg, Ni, and Nb anomalies did not extend farther than 0.6 km from the Prairie Creek lamproite, Arkansas. Haebig and Jackson (1986) noted that soil geochemical anomalies (Co, Cr, Nb, Ni) were detected in sand and soil immediately above lamproite vents in West Kimberley, Australia. Such anomalies could prove useful in the search for hidden olivine lamproites. Gregory (1984) used lithochemistry to distinguish olivine lamproite from leucite lamproite on the basis of Mg, Ni, Cr, and Co ratios.

Bergman (1987) suggested that olivine lamproites are generally enriched in compatible elements relative to leucite lamproites as a result of the abundance of xenocryst olivine in the former. Barren lamproites contain elevated alkali and lithophile contents (K, sodium [Na], Th, U, yttrium [Y], and zirconium [Zr]) relative to diamondiferous (olivine) lamproites. Diamondiferous lamproites possess twice the Co, Cr, Mg, Nb, and Ni and half the aluminum (Al), K, and Na as barren lamproites (Mitchell and Bergman 1991), and lamproites have anomalous titanium (Ti), K, Ba, Zr, and Nb compared to most other rocks. These components may favor the growth of specific flora or may stress local vegetation (Jaques 1998). The Big Spring vent, West Kimberley, Australia, is characterized by anomalous faint pink tones that reflect the growth pattern of grass on the vent (Jaques, Lewis, and Smith 1986).

Many kimberlites in the Colorado–Wyoming State Line District will not support growth of woody vegetation, resulting in open parks over kimberlite in otherwise forested areas. These same kimberlites may support a lush stand of grass delineating the limit of the intrusive. Distinct grassy vegetation anomalies over kimberlites in the Iron Mountain District, Wyoming, were used successfully to map

many intrusives (Hausel et al. 2000). The anomalies are especially distinct after a few days of rain in the late spring.

Some Siberian kimberlites support denser stands of larch (*Larix dahurica*) and abundant undergrowth of shrub willow (*Salix*) and alder (*Alnus*) compared to surrounding Cambrian carbonates. In central India, trees over the Hinota pipe are healthier, taller, and denser than those in the surrounding quartz arenite. This may be attributed to greater availability of K, P, micronutrients, and water.

Vegetation over the Sturgeon Lake kimberlite in Saskatchewan was tested for 48 elements; the kimberlite showed a consistent spatial relationship with Ni, Sr, Rb, Cr, manganese (Mn), and Nb, and to a lesser extent with Mg, P, and Ba; relatively high Ni concentrations occurred in dogwood twigs. In hazelnut twigs, Cr levels were greater than 15 ppm near the kimberlite but only 5 to 8 ppm elsewhere, and Nb was higher in hazelnut twigs. Sr and particularly Rb were relatively enriched in some plant species on kimberlite. The Sr was probably derived from the carbonates associated with the kimberlite, whereas the Rb was derived from phlogopite. Ni, Rb, and Sr distribution and Cr enrichment associated with Mn depletion in the twigs could be used to identify nearby kimberlite.

MINING AND MILLING

Economic diamond deposits depend on the average price of stones, the amount of waste material removed, mining methods, company politics, socioeconomics of the area, and many other factors. For example, a diamond deposit may be mined at a comparatively lower cost in a developing country because of the availability of an inexpensive labor force, although constructing an infrastructure in such an area could offset some of these benefits. In the United States, high labor and mining costs require higher-value ore for commercial operation; however, an infrastructure may already be available.

More than half of the world's natural diamonds are mined from kimberlite and lamproite and the rest are mined from placers. Economic cutoff grades are typically >0.10 carat/t (Jaques 1998), but the grade is highly dependent on mining costs and the value of the recovered diamonds. Thus the economic cutoff grade will vary depending on these factors. Average ore grades range from a high of 6.8 carats/t for Argyle to a low of about 0.15 carat/t for Prairie Creek, Arkansas. Some of the rich crater facies lamproite mined at Argyle yielded grades as high as 20 carats/t. Most economic deposits yield >30% gem-quality diamonds.

Commercial deposits include narrow dikes to pipes of 30 to 1,500 m across. Pipes range in surface area from 1 to 150 ha, averaging about 12 ha (Jaques 1998). Diamond mines possess resources in the neighborhood of more than 10 Mt to 350 Mt of ore, and the richest deposits contain reserves measured in the hundreds of millions of carats that are valued in the billions of dollars.

Open-pit diamond mines are typically designed to recover as little as 100,000 t to more than 10 Mt of ore per year. Annual diamond production may range from several thousand carats to a few million carats. For example, the Finsch mine, South Africa, produced about 5 million carats annually between 1981 and 1991, whereas annual diamond production for the extremely rich Argyle lamproite reached a record 39 million carats during the height of operation.

Diamond quality and size must also be considered in commercial operations. Lamproites appear to produce small diamonds with large percentages of colored stones. Many kimberlites yield a large range in diamonds, including some very large stones. For example, the average diamond from the Argyle lamproite is small (only <0.1 carat), and those from Ellendale lamproites are only 0.1 to

0.2 carat (Mitchell and Bergman 1991). The largest reported diamond from the Prairie Creek lamproite is 40.42 carats (Hausel 1998). Diamonds from some kimberlites, however, are extraordinary. The largest diamond ever recovered was the size of a human fist; it was mined from the Premier kimberlite, South Africa, and weighed 3,106 carats.

Bulk sampling is the initial step in evaluation of a commercial diamond deposit. If favorable, additional bulk samples are used to assist in establishing ore grade maps to aid in mine planning. Samples are taken on the surface and from drilling in order to achieve a three-dimensional view of ore grades. If the pipe is considered to be economic, planning is completed for an initial open-pit design and a mill placed near the pipe. Open-pit mining typically proceeds from a spiral road developed from the rim of the pit toward the center of the pipe. As mining proceeds, the country rock is cut back in steps to aid in supporting the high walls of the open pit. Mining in the pit may occur in an oval pattern or in a polygonal pattern (Bruton 1979).

As mining continues and the pipe narrows at depth, the open pit will shrink to smaller and smaller diameters. Mining operations may ultimately continue underground using bulk recovery by block caving. Fewer than 30% of diamond mines, however, are continued underground. And to do so, the diamond ore must be of relatively high value, because the cost of underground mining is considerably higher and the amount of ore recovered is considerably lower. Some kimberlites in Siberia and South Africa have been mined to depths of 1,080 m. Open pits may have mine lives of 2 to 50 years (Jaques 1998).

Following recovery of rock mined from open-pit operations, the ore is crushed and screened. Screening separates midsize from larger material rejects and from material too small to contain commercial diamonds. Decisions on the maximum screen size must weigh the cost of processing additional material with the loss of potentially priceless large diamonds.

The typical diamond mill has a basic flowsheet that begins with primary milling and continues to primary gravity concentration, secondary concentration, magnetic separation, and attrition milling. The final diamond extraction stage uses grease tables, electrostatic separation, or x-ray fluorescence extraction (Bruton 1979).

Placer mines are different. The size of a placer mine will vary from a small, one-person operation to a full-scale mine using bulldozers, scrapers, and dredges. Paystreaks are identified in streams or beaches; mining is then completed using small-scale or large-scale earth-moving equipment (Bruton 1979).

GEMOLOGY

The primary monetary value for diamond is as gemstones. Diamond prices vary considerably. There are approximately 5,000 diamond categories with prices that vary from \$0.5/carat up to several tens of thousands of dollars per carat (for large uncut or colored fancy diamonds) (Miller 1995). Many faceted diamonds are worth many times an equivalent weight in gold or platinum. Rough gemstone diamonds have values as high as 100 or more times that of industrial diamonds. After the diamonds are faceted, the value of the gem can increase another 10- to 100-fold, and the final placement of a stone in jewelry will again add another increase in the value of the stone. Thus, any mining operation should consider not only recovery of the gems but also the fashioning of the gems and marketing.

Diamonds are one of the more valuable commodities on earth, and arguably are the most valuable of all commodities based on weight. For example, some Argyle pink diamonds have sold for as much as \$1 million per carat (one carat weighs only 0.2 g [0.007 oz]). Thus, an equivalent weight in gold would be worth

only \$2.80 (at \$400/oz). The extreme value of diamond is due to its mystique, rarity, extreme hardness, high refractive index, and dispersion that can result in brilliant gems with distinctive “fire” when faceted and polished.

Four general types of natural commercial diamonds are recognized. These are *gem*, *bort* (poorly crystallized, gray, brown translucent to opaque), *ballas* (spherical aggregates formed of many small diamonds), and *carbonado* (opaque, black to gray, tough, and compact). Gem diamonds are further subdivided into *gem* and *near-gem* (low-quality gemstones).

The fashioning of diamond “rough” into a finished gem may require up to six steps that include marking, grooving, cleaving, sawing, girdling, and faceting (Hurlbut and Switzer 1979). Whether or not all of these steps are used depends on the size, shape, and quality of the rough stone.

The value of finished gem diamonds is judged by the “four Cs”: cut, clarity, carat weight, and color. The cut of a diamond can increase its value tremendously, and the better proportioned, polished, and faceted, the greater its value. When the girdle (base) and table of the diamond are proportioned correctly, the diamond will exhibit greater fire and brilliance.

Diamonds can be graded using the Gemological Institute of America’s color-grading system. This ranges from D (colorless) to X (light yellow). Each letter of the alphabet from D to X shows a slight increase in yellow tinge that is generally not apparent to the untrained eye (Hurlbut and Switzer 1979). Fancy diamonds are separated from colorless diamonds into groups based on color and intensity (Bruton 1978). Clarity is determined by the presence or absence of blemishes, flaws, and inclusions. One typical grading system ranges from Fl (flawless) to I₃ (imperfect) with intermediate grades of VVS₁ (very, very slightly imperfect), VVS₂, VS₁, VS₂, SI₁, SI₂, I₁, and I₂.

USE

The diamond industry is a multi-billion-dollar mega-industry. The unique physical and optical properties of diamond also make it indispensable and irreplaceable for many industrial uses in addition to personal adornment in jewelry.

Harlow (1998) and Olson (2001, 2003) describe many uses for industrial diamonds. Because of the mineral’s extreme hardness, industrial and synthetic diamonds are used extensively as abrasives in grinding, drilling, cutting, and polishing. Diamond also has chemical, electrical, optical, and thermal characteristics that make it the best material available for wear- and corrosion-resistant coatings, special lenses, heat sinks in electrical circuits, wire drawing, drilling, and many other advanced technologies. One significant future application will be in computer chips because of the diamond’s unmatched thermal conductivity and resistance to heat. A tremendous amount of heat can pass through diamond without causing damage.

Today’s speedy microprocessors run hot—up to 200°F—and microprocessors cannot run much faster without failing. Diamond microchips would be able to handle much higher temperatures that would liquefy ordinary silicon, allowing them to run at higher speeds. But manufacturers have not considered using the precious stone because it has never been possible to produce large diamond wafers affordably. The Florida-based Genesis and the Boston-based Apollo Diamond Company plan to use the diamond jewelry business to finance attempts to introduce diamonds into the semiconducting world.

At room temperature, diamond is the hardest known material with the highest thermal conductivity of any substance. Even though diamond is more expensive than competing abrasive materi-

als such as garnet, corundum, and carborundum, diamond has proven to be cost-effective in several industrial processes because it cuts faster and lasts longer than rival material. Synthetic industrial diamond is superior to natural industrial diamond in that it can be produced in unlimited quantities and tailored to meet specific applications. Consequently, manufactured diamond accounts for more than 90% of the industrial diamonds used in the United States.

According to the USGS, much of the synthetic industrial diamond produced domestically has been used as grit and powder (Olson 2002, 2003). The major uses were in machinery (27%), mineral services (18%), stone and ceramic products (17%), abrasives (16%), contract construction (13%), transportation equipment (6%), and miscellaneous uses (3%) (Olson 2002, 2003). Industrial diamonds are used in the production of computer chips; in construction; in the manufacture of machinery; for mineral and energy exploration and mining, stone cutting and polishing; and in transportation (infrastructure and vehicles). Stone cutting, along with highway construction and repair, are some of the largest users of industrial diamond.

Diamond has one significant limitation in industrial use: it reacts with iron at high temperature, causing the diamond to revert to graphite, which results in high rates of wear. In an iron-rich environment, diamond may be uneconomical to use in comparison to other conventional abrasives (i.e., aluminum oxide, silicon carbide, and boron nitride). Even though these are considerably softer than diamond, they are suitable as high-performance abrasives on ferrous work-pieces.

Diamond use has increased in both jewelry and industrial applications. One reason for the increase is the development of diamond synthesis technology, making it possible to produce diamond abrasives for specific applications. In the past, the only option was to use natural diamond, which had to be sorted by size and crushed, or by surface treatment such as rounding. Synthetic diamond abrasives, however, can now be produced under a controlled environment such that the shape of the crystal can be made irregular and sharp.

Diamond has many potential exotic applications. For example, the Venus probe was fitted with a transparent diamond window because diamond was the only material transparent to infrared light that could withstand the extreme cold and vacuum of space and the extreme high temperatures and atmospheric pressures of Venus’s atmosphere (up to 920°F, and pressures a hundred times that of Earth) (Ward 1979). Another exotic use gives new meaning to the family jewels. LifeGem in Illinois started manufacturing diamonds from cremated human ashes for jewelry for surviving relatives. The cost for a “family jewel” is reported to be more than \$2,000 for a 0.25-carat stone.

Diamond has applications in high-energy physics. Diamond windows are used in high-power lasers because of the high thermal conductivity, low absorption coefficient, and low value of temperature coefficient of refractive index. Diamond anvils are used in high-pressure research, where pressures greater than 4 megabars are needed. Such ultra-high-pressure research can simulate conditions in the core of the earth and on other planets.

Diamonds are also used in dental drills and surgical blades, and provide cutting edges that are many times sharper than the best steel blades. Since diamond has the greatest thermal conductivity of any material, pinhead-size gold-coated diamonds are used in high-capacity miniature transmitters that carry television and telephone signals.

Synthetics

Synthetic gem diamonds and simulants are becoming more common in the marketplace. These include cubic zirconia and moissanite.

Moissanite has twice the fire of natural diamond, is doubly refracting (unlike diamond and cubic zirconia, which are singly refractive), and has a hardness of 9.25—thus, both moissanite and cubic zirconia can easily be scratched by diamond. Double refraction is detectable in moissanite when viewing the front of the stone. The back facets will appear to be duplicated because of the double refraction—except when viewing down the optic axis where light is singly refractive. The optic axis is usually perpendicular to the table of moissanite; thus, one must observe the back facets through another facet to see evidence of double refraction.

Synthetic gem-quality diamonds can be produced in about 24 hours. Some stones weighing up to 3 carats have been produced for a few hundred dollars (uncut). Most are yellow, but some Russian stones are clear. In 1971, General Electric grew facet-quality synthetic diamonds that were nearly colorless (0.3 and 0.26 carats).

The colorless gemstones caused concern in the jewelry trade. Diamond simulants can be detected by a simple thermal conductivity test, but most jewelers were unprepared to distinguish faceted synthetic diamond from natural faceted diamond. Thus, DeBeers developed a diamond verification instrument known as Diamond-View, which uses UV fluorescence to distinguish colorless natural diamond from synthetic diamond. In addition, many synthetic diamonds examined by the Gemological Institute of America contain metallic inclusions in high enough abundance that they are able to attract a magnet. Nonfaceted synthetic diamonds exhibit a unique crystal habit of a cuboctahedron with a flat base. Synthetic diamonds also exhibit unusual dendritic and striated surface patterns. According to Shigley and others (1997), because of the technological challenges and high cost of production, it is unlikely that fashioned gem-quality diamonds larger than 25 points will affect the gemstone industry in commercial quantities.

FUTURE OF THE DIAMOND INDUSTRY

Diamonds have intrinsic value because of unique hardness, transparency, and thermal conductivity. Diamonds will be needed as long as there are industrialized nations. Without any foreseeable major economic disasters, the future of the diamond industry should remain strong.

As science and industry advance, additional applications for diamond are likely to be found in the electronics industry. Demand for diamonds for drilling in exploration for oil, gas, and minerals, and in the construction industries, is anticipated to increase. Some technological advances will demand both natural and synthetic diamond in the future.

For many years, the gem diamond industry was controlled by DeBeers—a monopoly so powerful that the diamond industry and DeBeers were thought by many to be the same. But the discovery of significant diamond resources outside of Africa has diminished DeBeers's control over the diamond market.

The first real threat to the monopoly occurred with the discovery of significant gem-quality diamond deposits in the former U.S.S.R. in the 1950s, but communistic bureaucracy could not compete with South Africa, and the Soviet diamonds did not greatly affect the market (Erlich and Hausel 2002). A major diamond discovery (Argyle) in Western Australia in the 1980s started the real first erosion of the monopoly. The Argyle deposit, however, though rich in diamonds, was dominated by industrial stones, and the gemstones recovered from the mine were small. Even so, the Australian company, Ashton Mining, decided to market their own production.

Some gemstones produced by Argyle included rare pink diamonds. Marketing strategies by the Australians were brilliant, resulting in the Argyle pinks becoming some of the more valuable gemstones on Earth. A large population of the Argyle diamonds

was also light-brown to brown and had been considered by the jewelry trade as industrial or near-gem. These were marketed as champagne and cognac diamonds, and the marketing strategy effectively resulted in these stones becoming highly sought gemstones. Even so, many of the Argyle diamonds were small and required the special cutting skills of gem cutters in India and Sri Lanka.

The next major diamond discoveries were made on the North American craton. This is the largest craton, with the largest Archon core, in the world. Based on the sheer size of the craton, and the many finds of detrital diamonds in glacial moraines, this craton should have been a high-priority target for diamond exploration groups. But for many years, the North American craton was ignored.

The discovery of economic diamond deposits in this craton was the result of unrelenting prospecting by a small group of geologists (Krajick 2001). The discovery set off the greatest rush in modern history and resulted in the development of a diamond industry in Canada.

Diamond production began in Canada following the capitalization of BHP's Ekati mine at more than \$800 million. A few other mines have now been developed, and in April 2004, the value of diamond production from Canada surpassed that of South Africa. This occurred in 6 years. In the future, many more discoveries of diamondiferous kimberlite can be expected in the North American craton. To date, as many as 500 kimberlites and some unconventional host rocks have been identified in Canada—early reports are that 50% contain diamonds—which could easily make the North American craton the primary source of diamonds in the near future.

The North American craton extends across the Canadian border into the United States, where several diamond deposits have been found. Even so, much of the terrain in the United States has not been prospected, or was only partially explored for diamonds. Many exploration targets remain inexplicably unexplored. To date, only two deposits have been mined for diamonds in the United States—one in the Colorado-Wyoming State Line District, and another near Murfreesboro, Arkansas.

Diamond exploration in the near future will continue to focus on Canada, where the geology and political climate are favorable. In addition to discoveries of diamonds in kimberlite and some lamproites, one might anticipate additional diamond discoveries in some unconventional host rocks such as minettes, alnoites, other lamprophyres, komatiites, and in particular, subduction-zone-related breccias.

One concern that has arisen is the potential production of relatively inexpensive synthetic gem-quality diamonds. Natural gem-quality diamonds, however, are also relatively inexpensive until they are faceted and mounted in jewelry. And it is human nature to want a natural gem rather than a synthetic stone or imitation. Gem-quality synthetic diamonds will probably not greatly affect the jewelry market.

CONCLUSION

With the current trend of investment, exploration, and progressive pro-mining atmosphere, it is anticipated that Canada will be a leading diamond producer for decades to come. The sheer size of the North American craton allows one to predict Canada to become the world's primary source for diamonds in the future. Unless there is a major change in attitude of the U.S. government and the population, little is expected to be produced in the United States, even though parts of the country are underlain by this craton. The importance of the North American craton in the future of the diamond industry has resulted in investments of hundreds of millions of dollars in exploration in North America.

Diatomite

Richard O.Y. Breese and Frederick M. Bodycomb

INTRODUCTION

Terminology and Definitions

The term diatomite is applied both geologically and commercially to the nearly pure sedimentary accumulation of diatom frustules—the microscopic skeletons of unicellular aquatic algae belonging to the class of golden brown algae, Bacillariophyceae. The sediments are fine-grained, highly siliceous, and consist primarily of amorphous opaline silica with only minor amounts of organic residue, secondary minerals, and codeposited nondiatomaceous or crystalline clastic debris. In the geological sense, the name diatomite implies sedimentary accumulations that have reached appreciable thickness, and consequently, when thick enough, such accumulations may have possible commercial potential. Although the term diatomite is popularly and inappropriately applied to any sediment in which there is an abundance of diatom frustules, alternative terminology is more correctly employed to describe less pure diatomaceous sediments (for example, clay-bearing diatomite or diatom-bearing clay). Synonyms in current usage include diatomaceous earth and kieselgur. More antiquated and obsolete terminology includes tripoli powder, tripolite, and infusorial earth.

Unusual Considerations Specific to Diatomite

Worldwide, diatomites occur within Tertiary to Recent lacustrine and marine sedimentary facies. Although diatomite is widespread throughout the world, deposits that contain high-purity, commercially versatile ore are uncommon. Physical properties of the diatom and of processed diatomite that provide unique commercial value in a broad spectrum of market end uses include ornate fine structure, low bulk density, high porosity, and high surface area. Properties of equal importance are mild abrasiveness, high absorptive capacity, insulating ability, relative inertness, high silica content, and high brightness. End use markets are diverse and range from insulating brick and absorbents through quality-sensitive filter aids and premium quality functional fillers.

Notwithstanding both the economic attractiveness of the specialty markets and the commercial versatility of the high-purity deposits, deposits of lesser purity are mined in many parts of the world for less demanding uses. Mining costs are minimized through open-pit quarrying, but in Europe, Asia, Africa, and South America, underground mining methods are also employed. Blasting is not required because diatomite is so soft and easily broken with mechanized equipment.

Following gentle crushing, the ore is dried, milled, and processed into one of three broad categories of products: natural (milled, not calcined), straight calcined, and flux calcined grades. Each of these principal categories is further subdivided into additional grades through particle-size adjustment of the powders. Agglomeration of particles, alteration of fine structure, and color change are achieved through calcination. The addition of flux before calcination further accentuates these changes.

The first industrial use of diatomite can be traced back some 2,000 years to the Greeks and to the use of diatomaceous earth in lightweight building brick and in ceramic pottery. It was not until the mid-1800s, however, that the unique properties of diatomite were first recognized and the market end uses investigated and developed. One of the most important of the early uses followed the development of dynamite by Alfred Nobel in the mid-1860s. Diatomite came to be used as a component of the explosive to improve stability and safety. Other early uses included low-temperature insulating and refractory bricks and as a component in fireproofing and insulating construction panels. During the 1920s, processing technology underwent a very rapid evolution with the development of calcination, flux calcination, and air classification technologies. Through these technologies, many different size and grade classifications could be made for the rapidly diversifying market applications and end uses.

Today, the application of processed diatomite for filter aid is the largest of the quality-sensitive end uses. Specific filtration uses include, among others, the clarification of beer, wine, and other liquors; vegetable oil; syrup and sugar; pharmaceuticals; motor oil; and swimming pool water. As a functional filler and extender, processed diatomite is ideally suited for use in paint, rubber, and plastic formulations. Other filler applications include uses as an antiblocking agent in plastic film, as an anticaking agent for fertilizer, as a thermal insulating material, as a catalyst carrier, in polishes and abrasives, as pesticides and fertilizer carriers, and for chromatographic supports. Throughout much of the world, diatomite is still used as a component of insulating brick and as an absorbent. Emerging applications include using diatomite as a natural grade insecticide and in the separation of fluid chemicals.

PRODUCTION, TRADE, AND RESOURCES

Production and Consumption Statistics

Estimates of world production vary by source, but including all quality grades, production in 1992 totaled in excess of 1.5 Mt. With the

*** Includes tripoli.

††† Sold or used by producers.

addition of Chinese figures, world production in the following decade ranged from 2.02 Mt in 1994 and 1999 to 1.95 Mt in 2003 (Taylor 1994; Antonides 1997; Dolley 1999–2003). Production trends are shown in Table 1. The average price per ton (Table 2), on a weighted basis by end use volume, rose from US\$ 219 in 1990 to a high of \$271 in 2001, followed by a drop to \$258 in 2003 (Taylor

1994; Antonides 1997; Dolley 1999–2003). The United States remains the dominant world producer, followed by China, Japan, Denmark, the former Soviet Union, France, and Mexico. According to the USGS, filter aids comprised 62% to 73% of the diatomite products sold or consumed in the United States during the past decade. Sales or consumption of fillers represented 11% to 17%;

insulation 2% to 4%; and other uses, including absorbents, additives, abrasives, and admixtures, 9% to 25%. The total value of diatomite products sold or used in the United States reached \$159 million for 2002 (Dolley 2002).

World Reserves

The world resource base of diatomite (inclusive of all qualities, and irrespective of end use suitability and proximity to infrastructure/markets) is vast, and there should be no worldwide shortage in the foreseeable future.

GEOLOGY

Mineralogy, Composition, and Chemical Properties

Diatomite is a fine-grained siliceous sedimentary rock or unlithified sediment of biogenic origin. It is chiefly composed of amorphous silica, present in the form of opaline diatom skeletons or frustules. Kamatani (1971) noted that the silica of recent frustules resembles amorphous silica gel, whereas the composition of fossil frustules resembles an opaline silica that has a lower solubility than the silica of its recent counterparts. Combined water held within the opaline structure of frustules varies among species and is reported to range as high as 9.6 wt % in some lacustrine forms to as low as 1.9 wt % in specific marine species (Tappan 1980; Lisitsyn 1967). In addition to silica, which is the major component, alumina, iron, alkali metals, alkaline earths, and other minor components are present (Table 3).

The silica content (as SiO₂) of diatomite samples, as determined on an organic-free basis, typically ranges from 80% to 90%, but silica contents as high as 97% have been encountered. As

determined through oxide analysis, iron, calcium, aluminum, titanium, sodium, potassium, and other elements are typically present in minor amounts of several percent or less (Table 3). Many elements are present in trace amounts (Table 4). Codeposited and secondary minerals of ten found in diatomites include clays, quartz, gypsum, mica, calcite, and feldspars. Less commonly, saltpre, pyrite, sulfur, manganese nodules, and vivianite and other phosphates are present. Chert and volcanic ash are often abundant constituents of the sediment. Common biogenic constituents include the tests of ostracods and bivalves, the siliceous remains of sponges, silicoflagellates, radiolaria, carbonized fossil leaves, and fossilized fish bones.

When chemical and mineral impurities are present in great abundance, alternative terminology is used to describe the sediment (e.g., sandy diatomite, clay-bearing diatomite, diatomaceous marl, and diatomaceous peat). These extraneous materials can affect the properties of the final product, including pH, the solubles present, density, and abrasiveness. In such cases, the ore's commercial suitability for some uses will be adversely affected, unless the contaminants can be removed or rendered insoluble through processing.

Thermal processing, or calcination, produces fundamental changes in the composition and nature of the opaline silica frustule. Within the trade, the term *calcination* has been loosely and incorrectly applied to the thermal processing of diatomite with or without the addition of a fluxing agent. Technically, the thermal treatment of diatomite is a sintering or agglomeration process achieved through incipient fusion. Calcination not only dehydrates the amorphous silica but initiates conversion of the opal to cristobalite. As much as 40% to 60% of the amorphous diatomaceous opal may be converted to cristobalite through flux calcination. As is discussed later, the

health issues related to the crystalline silica species present in diatomite products came under worldwide examination during the latter half of the 1980s, and health- and environment-related legislation was promulgated as a result. Other changes in physical properties that are induced through thermal processing are discussed in the sections that follow.

Morphology

The diatom is a member of a diverse group of single-celled, often colonial algae. The class is subdivided into two major groups: the Pennales forms have axial symmetry and the Centrales forms have radial symmetry. To date, more than 12,000 distinct species have been recognized (Tappan 1980).

Each cell possesses an internal, ornate siliceous skeleton consisting of two valves that fit together much like a pill box. The morphology of the frustules varies widely among species and serves as the basis for taxonomic classification. The surface of each valve is punctuated by a series of openings that comprise the complex fine structure of the frustule and impart a design that is distinctive to individual species (Figure 1). The size of the frustules ranges from 0.75 to 1,000 μm , large enough, as in the case of *Ellerbeckia teres* (previously *Melosira teres*) and some *Coscinodiscus* forms, to be visible with a hand lens. Most are in the range from 10 to 150 μm and require a microscope to be seen. The frustule of the living cell is covered by a jelly secreted by the algae and contains organelles typical of photosynthesizing plants.

Physical Properties

Low block density, typically ranging from 320 to 640 g/L, distinguishes diatomite from all other fine-grained sediments. High brightness, or whiteness, is an additional and distinctive attribute of nearly pure diatomites.

The fundamental chemical composition and intricate structure of the diatom frustule give diatomite unique commercial value and versatility in filtration and filler applications, unmatched by that of other natural forms of silica. Inherently, the fine particulate structure

of the diatom skeleton imparts low density and high surface area to milled powders. Ultimately, the fine structure also provides high porosity and permeability, along with the clarifying ability required in filtration applications. These same physical attributes impart high absorptive capability as well as low thermal conductivity. Although the skeletal structure is rigid and serves as an effective abrasive agent, the delicate particles tend to break and gently polish rather than scour. In filler and filtration applications that are sensitive to purity, diatomaceous silica remains relatively inert and lends only its physical properties. The melting point of diatomaceous silica ranges between 1,400° and 1,750°C.

Broad adjustment of physical properties is achieved through the thermal sintering process. Calcination reduces surface area by destroying the fine structure. Calcination and flux calcination progressively increase the specific gravity from 2.0 to 2.3; decrease the surface area of milled powders from ~10–30 m²/g to 0.5–5.0 m²/g; and increase the hardness of the silica from 4.5–5 to 5.5–6 (measured on the Mohs scale). The refractive index of natural powders ranges from 1.40 to 1.46 and increases to 1.49 through flux calcination.

Origin

Diatoms thrive in diverse habitats including marine, brackish, and lacustrine/stream environments. In addition, diatoms live in moist soils and on the surfaces of rocks and vegetation (Bradbury 1988). Species are also reported in exotic and specialized environments such as caves, snow and ice, hot springs, and in relatively dry areas (Patrick and Reimer 1966; Bradbury 1988). Basic biological requirements include sufficient moisture; sufficient exposure to light; an adequate physiochemical environment; and the availability of nutrients, trace elements, and an abundant silica supply.

Within aquatic environments that provide the basic requirements, diverse communities of planktonic, attached, and benthic diatoms can flourish and contribute to the geologic sedimentary record. The species composition of a living diatom community and—eventually—the sedimentary fossil community, as well as the dominance of individual species within a population, can depend on environmental variables such as water chemistry, pH, nutrient abundance, turbidity, temperature, and water depth, among others. Although some species are quite tolerant of environmental variance, the presence or morphotype of others requires or depends on specific ecological conditions. Both long- and short-term changes in population composition, in response to environmental change through time, can be observed within individual deposits. Such changes can produce several distinct types of diatomite ore within individual deposits, and these distinctions are important to investigate because varying types of diatomite ore may exhibit different physical properties, and thus varying suitability for specific end use applications.

Ecological conditions vary widely among lakes, and consequently, corresponding diatom populations can exhibit wide variation. Far from being solely of academic interest, characteristic assemblages can, in some cases, be used to fingerprint or recognize individual deposits and sources of commercial products. Figures 2 through 5 show several distinctive assemblages. Moreover, recognition of assemblages and changes in diatom population can assist in identifying individual beds within a single deposit, yield a useful mapping/stratigraphic location tool in extensively covered or structurally complex deposits, and aid in delineating commercial-quality ore bodies.

Deposits of diatomite reflect stable environmental and depositional conditions, as well as an optimum preservation environment. Although depositional rates vary, typical average thicknesses observed in deposits suggest yearly accumulations of no more than

Figure 5. Micrograph of a bog diatom assemblage from Pernambuco, Brazil

several millimeters of compacted sediment. Strata of significant thickness and high purity, therefore, indicate prolonged environmental conditions that favored high diatom productivity and were free of continuous and significant clastic contribution or mineral precipitation. Geologic preservation of the soft sediments requires protection from erosion, such as that offered by overlying volcanic rocks. Preservation also demands that the diatomite not be subjected to geological conditions that promote silica dissolution or diagenetic conversion of opaline silica to chert, porcellanite, or

quartz, such as through deep burial and exposure to high temperature and alkaline groundwater. Figures 6 and 7 show the distribution of many of the well-known diatomite deposits.

Marine environments favorable for deposition of nearly pure diatomite exist in submerged coastal basin areas and shelves that are isolated from significant sources of clastic contribution and in areas adjacent to upwellings where waters are nutrient and silica rich and biologically productive. Such areas occur today along the coastlines of California, Peru, and southwest Africa (Soutar, Johnson, and Baumgartner 1981). Seawater rich in both nutrients and silica has been found to contain as many as 1 million diatom cells per milliliter (Tappan 1980), and diatomites such as those in the Monterey Formation of California have been seen to contain as many as 1.28×10^6 frustules per cubic centimeter (Barron 1987).

Tertiary marine deposits are commonly found along uplifted Pacific Rim coastlines and are associated with interbeds of volcanic ash, clay, and clastic sediments. Thick marine deposits occur in the Monterey Shales and Sisquoc Formation in Santa Barbara and Kern counties in California; in the Miocene Tortugas Formation of Baja, Mexico; in the Miocene Pisco and Zapayal Formations along the Peruvian coast; and in the Miocene Funakawa Formation of northern Japan. Other marine diatomites and diatomaceous sediments occur in the Paleocene-Eocene Fur (Moler) Formation of Denmark; in Oligocene-Miocene sediments in Poland; in the Miocene Tellian Group (Beida Stage) of Algeria; in the Miocene Calvert Formation of Maryland and Virginia in the United States; and within Tertiary sediments in Spain, South Korea, Chile, New Zealand, and Java.

Lacustrine environments typically exhibit greater variability than marine environments in terms of pH, salinity, temperature, and nutrient content, but they can produce diatomite sections that are often tens of meters or more in thickness. Deposits commonly occur in Miocene to Recent volcanic environments and are associated or interbedded with volcanic rocks and sediments. This association is clearly demonstrated by deposits within the lake sediments of caldera moats, such as in the Trout Creek Mountains of Oregon; in lava-dammed rivers (e.g., Terrebonne, Oregon, and in the subsiding valleys of the Nevada basin and range); and within the lake sediments of volcanic maars in France. In many countries, including the United States, Brazil, Australia, and the Philippines, bog or shallow-pond deposits are found in Holocene to Recent nonvolcanic, marshy lowland terrains.

The thick diatom accumulations that are common in Tertiary sediments reflect the exceptional availability of silica from external sources such as runoff, groundwater seepage, and hot or cold springs, as well as from the internal regeneration of silica released from bottom sediments (Hurley et al. 1985). Groundwater that has percolated through silica-rich volcanic rocks and sediments undoubtedly supplies much of the required silica.

Distribution of Deposits

Diatomite deposits of both marine and lacustrine origin are commercially mined throughout the world. Although deposits occur commonly in Tertiary to Recent sediment facies, high-purity deposits suitable for versatile quality-sensitive products are uncommon. It should be noted that classification as high or low grade is dependent on the performance required by the ultimate application, not solely on purity. For example, although low-purity diatomite is unsuitable as a filter aid, it can make a high-quality absorbent.

Although marine deposits account for much of the worldwide production, mining activities at lacustrine deposits are far more numerous. In the United States, diatomite is mined in California, Nevada, Oregon, and Washington. In Canada, impure diatomite is

Figure 6. Diatomite deposits and processing plants in North and South America

mined in British Columbia. Information about foreign producers and production is often lacking or available only as estimates. Notable mining operations in Europe are in France, Denmark, and Spain; as well as in Iceland. Substantial production is reported for the former Soviet republics and the Czech Republic, but little specific information is available about mines and production facilities. African production is reported for Algeria and Kenya. Historically, the U.S. Bureau of Mines reported mining in Morocco. In Asia, mining operations are known in Japan, South Korea, and China. Farther south, production is reported in Australia and New Zealand. In Latin America, Mexico leads production, followed by Peru, Argentina, Costa Rica, Chile, Brazil, and Colombia.

North America

North American production is dominated by the United States where at least five companies operate at 10 locations in four western states. Since 1990, the industry has experienced notable changes in ownership, closure of two operations, the startup of a new operation, and the reopening of an operation that had ceased production. These include the divestiture of Manville Corporation's diatomite operations to Celite Corporation, a subsidiary of World Minerals; Celite's acquisition of CR Minerals' operation in Nevada; the closure of Grefco's Lompoc operations; the closure of the Oil-Dri Corporation facility in Oregon and its 2003 acquisition of operations at Taft, California; the development of high-brightness natural grade diatomites by DiaSource in Oregon for insecticides, fillers, coatings, and the control of pitch in paper manufacturing; and the 2002 attempt by the Atlas Minerals subsidiary Whitecliffs to reopen an operation in Arizona for filler specialty markets such as calcium silicates, asphalt, extenders, and insecticides. At the time of publication, Alleghany

Figure 7. Diatomite deposits and processing plants in Africa, Asia, and Oceania

Figure 8. View showing portion of one of EaglePicher Filtration & Minerals, Inc.'s diatomite quarries at Lovelock, Nevada

Corporation announced it had signed a definitive agreement to sell World Minerals Inc. to Imerys USA, Inc.

In 2002, Nevada became the major producing state in North America. Mines in Nevada include those operated by EaglePicher Filtration & Minerals, Inc., at Clark Station, Lovelock (Figure 8), and near Fernley and Brady; the Grefco operation at Basalt; the Celite Fernley quarries and mill (previously owned by CR Minerals); and the Molten Company facility constructed during 1987 north of Fernley. Until 2002, California was the major producing state with the majority of production sited near Lompoc in Santa Barbara County. The operations at Lompoc consist of the mines and mills owned by Celite Corporation. The marine diatomite at Lompoc is approximately 300 m thick and is the largest center of production in the world. Other operations in California include Grefco's facility in Shasta County, constructed near Lake Britton during 1985 and 1986, and the Oil-Dri Corporation facility that

Courtesy of EaglePicher Filtration & Minerals, Inc.

Figure 9. View of EaglePicher Filtration & Minerals, Inc., quarry at Vale, Oregon

Figure 10. View of EaglePicher Filtration & Minerals, Inc., processing plant at Vale, Oregon

mines lithified diatomaceous earth near Taft for the manufacture of cat litter, pesticide carriers, and oil absorbents.

During 1986, EaglePicher Filtration & Minerals completed construction of the Vale, Oregon, facility (Figures 9 and 10) in Malheur County. Oil-Dri Corporation has reported ending its production of absorbents and agricultural grades of diatomite in Lake County, Oregon. The Celite Corporation operates several mines and plants that produce flux calcined filter aids at Quincy in Grant County in Washington State.

Well-known deposits occur throughout the western states in many of the Tertiary formations that contain lacustrine facies. Deposits have been known for many years in the Truckee, Desert Peak, Carlin, Esmeralda, and Panaca formations of Nevada; within the Juntura, Drewsey, and Trout Creek formations of Oregon; and in the Quincy and Squaw Creek portions of the Yakima Basalt Subgroup in Washington. Diatomites and diatomaceous sediments are also present in the Banbury Basalt and Idaho Formation in Idaho, near Dorris and Lake Britton in northern California, and

within the Quaternary age basin sediments in Utah. Along the U.S. East Coast, bog-type deposits have been identified in New Hampshire, New York, and Florida.

Production in Canada has historically centered on bog-type deposits in Nova Scotia, and more recently on the lacustrine diatomites at Kamloops in British Columbia. The production in Nova Scotia has ceased. Because of the elevated clay and contaminant content of the British Columbia deposit, production has been directed toward manufacture of absorbents, fillers, carriers, and refractory/insulation bricks.

Celite Mexico is the largest of the Latin American producers, with mines and processing facilities near Guadalupe in Jalisco State in Mexico and in Chile. In Mexico, numerous other lacustrine deposits occur in the states of Mexico, Michoacan, and Tlaxcala. Extensive, although impure, marine diatomite deposits crop out for many kilometers along the Baja coast.

South and Central America

Diatomite deposits in Brazil occur along the East Coast in the states of Ceara, Rio Grande do Norte, Bahia, Pernambuco, Santa Catarina, and Sao Paulo. Without exception, the deposits are accumulations in bogs or shallow ponds that contain abundant organic matter that must be burned out through an ignition process. In the past, organic matter was removed in stationary, wood-fired kilns located at or near the deposit. Size classification and/or flux calcination was then used to further process the organic-free diatomite into fillers and filter aids.

Commercial production continues to be reported in Argentina. Historically, lacustrine deposits have been mined in Neuquen, La Rioja, and Rio Negro provinces. Deposits are also known in Catamarca, Chubut, Salta, and Jujuy provinces.

Production in Chile centers on the numerous lacustrine deposits, typically contaminated by salt, near Arica in the northernmost part of the country. Celite acquired these operations in the past decade. Other lacustrine deposits occur throughout Chile from the northern province of Tarapaca south to the province of Chiloe. Marine ores were previously mined near La Serena, 400 km north of Santiago.

Elsewhere in Latin America, production is reported for Peru and has been reported at the Laguna de la Herrera deposit in Colombia. In Peru, numerous lacustrine and marine occurrences are found along the West Coast and in the western Andes. The most notable of these are the marine deposits near Pisco and the marine phosphate-bearing sediments at Bayovar. Undeveloped lacustrine deposits occur to the south of Quito, Ecuador, and at Lake Brava in Venezuela.

Europe

Deposits in France, the former Soviet republics, and the Czech Republic are the most significant of the European diatomite sources. Although production rates are significant, fundamentally different products may be made from the material mined at the various locations. Production in France focuses on premium quality filter aid and filler. Historically, production from the former Soviet republics has been reported to focus on the construction and refractory product industries. Spain and Iceland are also major producers of filter aid and filler. Denmark is the largest producer of moler earth, a diatomite-clay mixture used in the manufacture of insulating brick, absorbents, carriers, and a variety of powders and granules.

Tertiary lacustrine deposits occur throughout the Massif Central of France. Carbonisation et Charbons Actifs SA (CECA), a subsidiary of Atofina, has operations at Murat and to the south near

Privas at St. Bauzile. Celite Corporation mines this same deposit at Murat as a source for filter aids and fillers. The largest of the Spanish mines is operated by the Celite Corporation near Elche de la Sierra. Although carbonate-bearing, the lacustrine ores are bright and produce a broad spectrum of quality filler products. Marine diatomites crop out near the coast in the south of Spain.

Germany was the first country to commercially produce diatomite, although production reportedly ceased during the past decade in the Luneburg Heath Area of Lower Saxony. Other deposits also occur in the Klieken Area and in the Vogelsberg Mountain area of Bavaria. In Italy, lacustrine diatomites have been mined in the Viterbo District.

In northern Iceland, a joint venture between the Icelandic government and the Celite Corporation employs dredging methods to extract the diatomaceous muds that lie beneath Lake Myvatn. From the dredging barge, the muds are pumped as a slurry to landside hydrocyclones where unwanted volcanic ash and other contaminants are removed, and then on to settling ponds. Geothermal steam is used to dewater and dry the resulting crude ore before calcination or flux calcination.

Marine moller earth is mined on the isles of Mors and Fur in Denmark. The crude ore contains up to 30% plastic clay, precluding its use for the production of filter aids. Some lacustrine diatomite has been mined in Portugal at Couto Mineiro de Jardim, but production is minor. Another deposit is located near Rio Maior.

Although production is reported for Romania, the Czech Republic, and the former Soviet republics, little information is available about deposits and processing facilities. Reserves of marine and lacustrine diatomite in the former Soviet republics are believed to be large and to occur in the central Volga region, in Georgia, the Ukraine, Armenia, and in the St. Petersburg area. Mining in Romania has historically been at Adam Clisi, Pătrăcele-Buzău, and at Minis Arad. In Hungary, lacustrine diatomite has been mined at Erdőbénye. Diatomite mining in Yugoslavia has centered on the Prilep and Križva Palanka deposits. Impure marine deposits occur in southeast Poland. Diatomite has also been mined in Bulgaria near Gurmen in the Blagoevgrad District.

Africa

Deposits of marine diatomite occur in Algeria at Sig and at Mostaganem. The Sig diatomite, which is characterized by elevated carbonate content, has been mined by Societe des Diatomites d'Algerie using underground methods. Numerous lacustrine deposits are found in the Kenyan Rift Valley. Although most of the deposits are poorly known or not commercially significant, African Diatomite Industries Ltd. has mined the diatomites at Soysambu and Kariandusi. Small lacustrine deposits occur at several locations in South Africa. During the 1980s, annual production was reported from the Witdraai deposit in the northern part of Cape Province. Lacustrine diatomite has been mined in Morocco at Awinat. Elsewhere in Africa, impure lacustrine deposits are known in Angola; Djibouti; central Ethiopia; Nigeria; Zimbabwe; and within a coastal belt in Mozambique.

Asia and Oceania

Until the past decade, the annual production rates for China and Japan were available only as rough estimates. Both countries, however, now report significant production and are respectively ranked second and third largest in world production.

China is reported to have more than 50 diatomite occurrences located in 14 provinces (Crossley 2000) and to have 34 mines, with major mines located in Inner Mongolia and in Hebei, Jilin, Zhejiang, Sichuan, and Yunnan provinces (Fu Taizhi, personal commu-

nication). The largest and most commercially significant of the high-purity-deposit areas in China occur in Jilin Province near the border with North Korea. Deposits in this area have been jointly commercialized with Celite Corporation. The lacustrine diatomites are extensive and must generally be mined by underground methods. Many other, lesser-known lacustrine deposits occur in Jilin as well as in Heilongjiang Province. Vast reserves of clay-bearing lacustrine diatomite are present in Zhejiang Province and scattered throughout southwestern Yunnan Province.

In Japan, more than 70 lacustrine and marine deposits occur on the islands of Honshu, Hokkaido, and Kyushu. Hakusan Industry, Isoraito Mining, Nittetsu Mining, Sakamoto Mining, and Showakagaku are major producers in Japan (Crossley 2000). All production in the country is controlled by Japanese companies.

Both marine and lacustrine deposits occur in southeastern South Korea. Filter aids, fillers, and other grades have historically been produced at facilities located near Pohang. Although no production is reported for the Philippines, bog-type lacustrine deposits are present. Impure, clay-bearing lacustrine diatomite occurs in Vietnam and in Thailand. The deposits in Vietnam are reportedly being examined for development. Deposits are also known in Indonesia.

In Turkey, numerous deposits of lacustrine diatomite occur in the central portion of the country. Elsewhere, Kamal Abad reportedly produces diatomite in Iran.

Mining of lacustrine deposits in Australia has been undertaken in New South Wales, Victoria, Queensland, and Western Australia. Marine and lacustrine diatomite occur on the North and South islands of New Zealand, but only small-scale production has been reported at several of the deposits.

TECHNOLOGY

Exploration and Evaluation

Exploring and evaluating deposits requires that geology, mining feasibility, and processing feasibility be integrated with the determination of the ore's suitability for the products desired to meet market needs. During the course of these studies, the fundamental elements of an evaluation program must include identification of ore strata and determination of strata mineability (i.e., number, thickness, areal continuity, to mine potential, and the degree of mining selectivity required). In addition, processing requirements—such as the equipment required and the process flow, the determination of economic marketability, and an assessment of logistics, including proximity to utilities, transportation, and work force—must be determined. A basic understanding of these elements will benefit the geologist in designing, guiding, and interpreting the sampling program. There are many diatomite deposits in the world but very few that are of high purity with commercial value. As a high priority, the suitability of the diatomite for product/market end uses must be determined.

Deposits of diatomite occur in Tertiary marine and lacustrine sedimentary facies throughout the world, and many such facies are well described in geologic literature. Aerial photographs can be reviewed to augment study of the literature when selecting target areas. After a promising target is identified, a sequence of sampling programs is initiated. A typical exploration program consists of several sampling phases that may lead to the eventual determination of measured resources or proven reserves. The sampling phases, which are punctuated by go-no-go decisions to proceed, would be followed by development and quality assurance sampling immediately before and after the commercialization of the deposit.

Initially, very widely spaced surface samples are collected and used to determine the general quality of the exposed diatomites, the

quality variations across the deposit and between individual beds, and the tonnage potential. This also permits areas that warrant priority investigation to be identified. During this phase, representative samples are collected from well-exposed outcrops or shallow trenches that have been excavated to adequately expose the near-surface beds. In conjunction with surface mapping, sample testing results and data from microscopic examination of the stratigraphic sequence can be used to direct continued effort.

If the initial sampling, sample test results, and mapping results are encouraging, phases of progressively closer spaced sampling can be considered. Unless the sediments are naturally well exposed, subsurface potential must be determined by drilling or by excavating shaft-like pits. Geophysical prospecting techniques such as very-low-frequency electromagnetic (VLF-EM) and seismic methods are unable to directly distinguish diatomite from other sediments, but they may permit the rapid, if indirect, interpretation of subsurface geology. Consequently, geophysical methods can be used in conjunction with surface data to guide the selection of priority targets and the location of drilling sites.

Final sample spacing is dependent on the continuity of the beds and the quality variations that are observed. To permit pit design and mine planning, a final spacing pattern of less than 50 m to as much as 100 m is generally used. During core drilling, care must be taken to avoid contaminating the core with drilling fluids, and the core diameter must be large enough to ensure high recovery. BQ (36.5 mm) or NQ (47.6 mm) diameter coring using triple tube wireline usually minimizes drilling problems and yields sufficient sample for testing.

If the results of sample tests indicate commercial-grade ore, and mining is determined to be feasible, bulk samples are collected to determine plant-scale performance. Other special samples may be required before mining begins. Even though this is the final phase of exploration sampling, pit-face quality assurance sampling must be undertaken during active mining.

Specialized sampling techniques can be employed when drilling is unnecessary. Where crude ores are soft and less than 5 m thick, hand augering with extension rods is effective, although the auger bucket must be emptied frequently and the cuttings laid out carefully for sampling. Mechanized augering works well in soft, wet diatomite. For sampling muds and oozes, augering can be done with a peat bog sampler.

The goal of optimum sampling is to delineate potential ore strata of uniform or nearly uniform quality. This includes determining the suitability of the ores for product application as well as the delineation of waste strata. Program design thus requires that critical specifications and product/market requirements be identified. Integrating these factors within sampling programs permits the program to be guided through the recognition of critical variations in ore quality. Appropriate qualitative yardsticks must be selected to judge results relative to industrial and health standards as well as to competitive commercial products. Because ore quality can vary between strata in a deposit, or across a deposit within a single stratum, sampling intervals and methods must be selected to maximize recognition of quality variation and to avoid sample bias.

Specialized testing of ore samples and of prepared test product samples is undertaken to examine the suitability and performance of an ore for specific product applications. Testing of physical properties and milling performance can include the determination of lab-scale milling recovery, density of dry milled powder, wet density, particle-size distribution, brightness, flow rate, clarity of filtrate, surface area, abrasiveness, Hegman value, and other properties related to specific market applications. Other testing examines chemistry and composition, including major and minor oxides, trace elements,

heavy metals and toxic compounds, pH, soluble substances, and the determination of crystalline silica content. In addition, many countries require products that contact food and beverages to pass stringent Food Chemicals Codex specifications.

Mining, Milling, and Thermal Processing

Mining Methods

Throughout most of the world, the lower cost of and higher recovery from open-pit quarrying relative to underground mining encourages operators to use surface mining methods. Where the diatomite sequence is thick, benches from 1.5 to 15 m in height are developed. Benching not only facilitates the removal of ore and waste but also permits immediate access to many ore layers and provides the opportunity to blend layers with differing characteristics. Notable exceptions are underground mines in Europe, South America, and Asia, and the dredging operation at Lake Myvatn, Iceland.

Prior to mining, the ore strata are carefully identified in the quarry faces through sampling and evaluation programs that determine and confirm the suitability of each individual stratum. The ore-grade strata can then be rated by quality and carefully segregated from the lower quality waste units using mechanized equipment. Because diatomite is a soft, easily broken sediment, ores are typically dozer ripped or broken from the face by power shovel. Blasting of the ores is neither needed nor possible because of the inherent softness of commercial quality diatomite, its porosity, and its absorptive nature. The broken material is loaded by front-end loader or belt loader into haul trucks for transport to either the crude storage area or the waste piles.

Typically, the moisture content of unprocessed ore ranges from 30% to 60%. Where the climate is favorable for solar drying, significant cost savings can be achieved by reducing moisture before milling. Crude grades may be blended or used separately depending on the final application.

Milling Methods

The objectives of milling are twofold: to disaggregate the crude ore into individual diatoms while preserving the delicate diatom structure, and to remove as much nondiatomaceous contamination as possible. Ore is gently crushed in spike rolls and hammer mills to reduce feed size to approximately -1.27 cm. The crushed feed is then conveyed by heated air into milling fans and simultaneously milled and partially dried. Secondary milling and drying further reduces the moisture content. The dried material is sized by a series of air separators and cyclones, the oversize recycled, and the coarse waste removed. Without further processing, the sequential milled products consist of coarse fractions that may be used for filter aids and finer fractions that are sold as filler grades.

Thermal Processing Methods

Diatomite is thermally processed, or calcined, to achieve fundamental adjustment of particle structure and particle-size distribution. Calcination in a rotary kiln, with or without the addition of a fluxing agent, removes organic matter and reduces the percentage of fine structure through incipient fusion, thereby reducing surface area through the loss of fine structure (Figures 11 and 12). Average particle size is increased through sintering or agglomerating the individual diatoms and fragments. After additional air classification, the coarser fractions or cyclone products are collected for use as filter aids. The finer baghouse products are used as fillers. Permeability and flowthrough rate of the powders used for filtering are thus increased and a more diverse spectrum of products is made possible

through additional milling and classification. Calcination produces a color change as well as the modification of other properties described previously.

Diatomite is calcined without adding a fluxing agent at temperatures that range from 870° to 1,100°C to produce pink or off-white straight calcined product grades. The straight calcined grades of filter aid exhibit flow rates faster than the natural grades but achieve lower filtrate clarity.

Calcination at temperatures up to 1,200°C with a fluxing agent added produces white-colored product and further increases the flow rate of the coarse fraction filter aid grades. The fine fraction recovered from the baghouse is sold as white fillers. In the United States, soda ash (sodium carbonate) is used as the fluxing agent. Historically, sodium chloride has been used as a fluxing agent elsewhere in the world. Temperature, amount of flux used, and retention time in the kiln are used to control the particle-size distribution. In general, fluxing agent is added at 3 wt % to 7 wt % of the feed.

In the manufacture of calcined absorbents, diatomite ores are crushed to -1.27 cm, the fines removed, and the coarse fraction calcined at temperatures lower than those employed for calcinations of filter aids. The product is then crushed and screened.

Testing and Specifications

The factors that affect the ultimate properties of processed diatomite products are complex and interrelated; they include the fundamental composition and nature of the diatomite crude ore as well as each of the handling and processing steps that follow mining. Thus, the quality of mill and kiln production can vary, and the implementation of quality and process control procedures is required to ensure that uniform products of acceptable quality are produced.

Control of the manufacturing process can be achieved by the periodic testing of in-stream and finished-product samples and consequently adjusting processing variables such as kiln temperature, flux addition, fines removal, and crude blends. Laboratory testing of samples also permits product performance to be quantified and commercial acceptability to be confirmed. By using standardized testing methods, the commercial quality of a product sample can be judged relative to commercially accepted application-specific specifications and to the performance of standard samples. Stringent product specifications must be established, tested for, and met for each end-product grade.

In filtration applications where filter aids must achieve satisfactory clarity at a reasonable flow rate, the flow rate and clarity performance of a filter aid sample can be tested under controlled laboratory conditions and measured directly. Because diatomite is purchased on a weight basis and used by volume, wet cake density must also be determined. The particle- and pore-size distributions, which reflect the ability to trap suspended particles, are also directly measured, as well as are the pH and resistivity of the powder. These latter tests indicate the presence of soluble substances that can affect the quality of the filtrate. Trace element analysis using Food Chemicals Codex methods and limits must also be conducted on food-, beverage-, or cosmetic-related products. With the advent of health-related labeling requirements, the abundance of free crystalline silica is routinely determined to ensure compliance with all regulations. Brightness is tested using the methods of the Technical Association of the Pulp and Paper Industry (TAPPI) or the General Electric Company to determine the whiteness of a product relative to a magnesium oxide or barium sulfate standard. Although brightness is only of aesthetic value for filter aids, the whiteness has great importance for many filler applications.

Samples of functional filler products are typically tested for density, TAPPI brightness, and particle-size distribution. Additional

Figure 12. EaglePicher Filtration & Minerals, Inc., flux calcined filter aid showing the reduction of fine-structure resulting from thermal processing

testing for paint application can include the determination of Hegman value or fineness, and the liquid vehicle demand expressed as oil or water absorption. The abrasiveness of the product for paper applications can also be measured using the Valley Iron method.

Nearly all applications have their own unique requirements, formalized specifications, or both. As a result, testing methods have been developed for predicting the suitability of products. Evaluation can often be achieved using simple, improvised testing procedures

through which small samples of product are made and pertinent characteristics of the final product can be compared to accepted industrial norms. Similarly, comparison can be made between the performance of traditional materials used in a product formulation and the performance of potential substitutes.

The following test procedures and specifications are available through the American Society for Testing and Materials (ASTM), the U.S. military, and the agencies or governments of other countries:

- ASTM D686-93. *Standard Test Methods of Qualitative Examination of Mineral Filler and Mineral Coating of Paper*
- A-A-59239 NOT 1. U.S. Military Specification, *Diatomaceous Earth*
- BS EN 12913. British Standard. *Products Used for Treatment of Water Intended for Human Consumption: Powdered Diatomaceous Earth*

MARKETING

Worldwide, the production of diatomite is reported for at least 29 countries. Seven countries and a few producers dominate world production. The major producers achieve distinct marketing advantage in the domestic and export marketplaces by offering the customer integrated technical and sales assistance. The ability to provide such services relies largely on technical knowledge of the customer's process and product needs as well as on the ability to deliver a broad spectrum of application-specific products. Related services include supplying reliably available products through well-developed distribution systems and worldwide marketing presence, and furnishing product development and technical support from research and development organizations. Throughout the world, the large producers have established trade or brand names that are synonymous with reliable quality. Many smaller producers compete successfully with the larger manufacturers by supplying local niche markets at lower prices. Commonly, these smaller producers supply local market requirements for which demanding quality specifications and technical sales service are not required.

Uses, Grades, and Specifications

The unique physical properties of the diatom make diatomite and processed diatomite powders suitable for wide-ranging industrial applications. Early uses of diatomite blocks and powders focused on absorption, abrasion, and insulation applications, but the use of diatomite as a filter aid in the mechanical separation of suspended solids from fluids now surpasses all other specialty applications in terms of tonnage. Notwithstanding the importance of filter aid uses, specialty functional fillers and diatomite-based synthetic silicates supply significant markets. Insulation, granulated or powdered absorbent, and agricultural and construction grades continue to serve high-volume markets that can utilize more highly contaminated diatomite that is unsuitable for filtration purposes. Use of diatomite in fluid chemical separation, in natural insecticides, and in granular soil amendments are applications where growth is anticipated.

Worldwide statistics on usage are generally unavailable. Some 1993 estimates suggest filter aids represented 45 % of worldwide consumption, including molar, and that more than 25% was used as filler, 17% for insulation, and roughly 11% for absorption and other applications (Roskill Information Services Ltd. 1994).

Filtration

According to the USGS, 68% of the diatomite produced, sold, or used in the United States in 2003 was for filter aid (Dolley 2003).

The physical and chemical properties required of filter aid-quality diatomite are demanding and must ensure the clearest possible filtrate, a high flow rate of fluid through the filter cake, and a long cycle duration before the filter cake must be replaced. Optimum permeability and flow rate–clarity characteristics of the filter cake are achieved by careful control of the particle-size distribution and porosity of the filter aid cake. These properties are controlled and adjusted through thermal sintering and particle-size classification to produce a broad spectrum of filter aid products and filtering characteristics. Table 5 lists the properties of a range of products. As a rule of thumb, the ability to remove small particles from a fluid decreases as the permeability of the filter cake increases. In general, natural products exhibit slower flow rates but achieve the greatest clarity. Straight calcined and flux calcined products, respectively, exhibit faster flow rate and lower clarity than the natural products. For special applications, diatomite is mixed with cellulose fiber and can be surface treated and acid washed.

The proper grade of filter aid is selected based on the minimum size of the suspended particle that must be removed and on the clarity of the final filtrate that must be achieved. The optimum grade will provide the fastest flow rate while achieving acceptable filtrate clarity. Several filtration steps, each utilizing a specific grade of filter aid, may be required. Nearly neutral pH and low solubles content of the filter aid powder are necessary to ensure that the filter cake is chemically inert and the final filtrate is high in purity.

Diatomite filter aids are used in a wide variety of food and nonfood filtration applications. Brewing, sugars, fats and oils, wines, pharmaceuticals, and fruit juices represent several of the largest food-contact applications. Major industrial end users include the petroleum industry, inorganic and organic chemical manufacturers, the nonferrous metals industry, and industrial wastewater treatment operations. Swimming-pool water filtration is a major consumer market end use.

Fillers

As a class of products, fillers can be divided into the two general categories of nonfunctional and functional, depending on the role that the additive plays in the ultimate performance of the final product. Nonfunctional fillers are used as bulking agents and as cost-reducing agents and extenders. Functional fillers are working additives that alter and enhance the properties of the final product; they may also improve the manufacturing process itself by conditioning the ingredients. The physical properties of functional fillers are tailored to meet the needs of individual applications, and thus must be tightly controlled to meet the rigorous requirements of each end use. Many of the functional fillers command a high sales price.

Most diatomite manufacturers produce filler application grades from baghouse fines. Historically, filler products were developed from the fines derived from filter aid production. Today, the filler applications are highly demanding and filler products must meet rigorous specifications and physical property requirements, and a broad spectrum of natural, calcined, and flux calcined grades are made to meet the needs of diverse end uses. Ideally, filler grades are insoluble and inert in most chemical processes, exhibit low bulk density while maintaining small particle size, and provide suitable particle shape and size distribution. The particle size of functional fillers generally ranges from 1 to 50 μm . Many other properties may be relevant for specific applications, such as color, surface area, liquid absorption capability, abrasiveness, particle rigidity, high melting point, and

porosity. Although many minerals are crushed and sized as fillers, the inherent properties of diatomite are well suited for, or can be readily modified for, specific filler applications. Table 6 gives typical properties of some commercial fillers.

Because the uses for diatomite fillers are numerous, only a few of the notable applications are discussed here.

Paints and coatings are among the most important of the filler end uses of diatomite. Functionally, the diatomite filler acts to extend more costly pigments and serves as a flattening agent that reduces both the sheen and gloss of the dried paint surface. The small size and

irregular shape of the particles serve well to roughen the paint film, imparting a matte finish as well as tooth for better adhesion of top coats. Toughness and durability of the film are also increased. Rigorous requirements for brightness, pH, absorption, refractive index, particle size, and chemical stability must also be met.

In polyethylene film, the particulate structure and the optical properties of diatomite fillers make them effective antiblocking agents. When added to the film during manufacture, the small and irregularly shaped particles mechanically separate adjacent sheets and prevent adhesion.

In other plastics, diatomite is used to reduce cost and improve heat resistance and surface finish. Diatomite also reduces mold release resistance and improves abrasion resistance.

Absorbents

For more than 50 years, diatomite of lower purity has been used to absorb liquid spills. Both granules and powders of various grades are manufactured and may be calcined to increase hardness, improve durability after absorbing a fluid, and reduce the tendency to produce dust. Since its early use as “floor sweep” absorbent, numerous industrial, environmental, and household spill-control applications have emerged that utilize the low bulk density of diatomite as well as its inherent high surface area and porosity and the resulting ability to absorb and retain up to 2–3 times its own weight in liquids. Diatomite can be used to absorb a wide variety of liquids including water, oil and grease, and chemicals, with the exception of hydrofluoric acid. Floor sweeps and pet litters, particularly for cats, are two of the large volume and widely known applications. Diatomite has been used in areas such as stables to absorb liquids and, reportedly, to control flies.

Soil Amendments

Granules of calcined diatomite are increasingly being used as a high-end soil amendment. Important properties include granule durability and water retention and release. Research has indicated that 10% incorporation by volume in soils can reduce irrigation requirements by up to 50%. As a soil amendment, diatomite is used for preventing soil compaction in sports turf, improving root growth, lessening transplant shock for landscape plantings, and reducing water and chemical consumption for all turf and ornamental applications. New developments include adding diatomite to create specialty soil blends for hanging basket soil and rooftop garden soil (P. Lenz, personal communication).

Natural Grade Insecticides

The use of diatomite dusts in commercial products designed to control insects and mites within stored agricultural products is widespread throughout the world. Public and governmental pressure to reduce reliance on chemical insecticides that are harmful to mammals would appear to offer growth potential for this application and others such as soil and structural fumigation. Although several mechanisms have been proposed to explain diatomite's effectiveness as an insecticide, the adherence of the particles to the waxy surfaces of insect pests and the absorption of body fluids are believed to cause death by dehydration (Crossley 2000). Product effectiveness may be enhanced by adding silica gel and treating with heat.

Cement, Concrete, and Asphalt

Diatomite has been used only to a limited extent in the United States as a supplemental silica source in cement kiln feed where it has been used in conjunction with traditional raw materials. Provided that the diatomite source is within economic transport distance of a cement plant, the chemical composition, fine grain size, and relatively low fusion temperature of diatomite are attributes that may potentially yield advantages in the manufacturing process. Potential benefits that should be considered include reduction in feed and clinker grinding, ease and homogeneity of reaction, energy savings in calcination, mitigation of process bottlenecks, and improvement of the properties of finished product and finish characteristics of the cement.

In concrete, mortar, plaster, stucco, and grout, diatomite filler can improve plastic and hardening properties; enhance cohesi-

ness, homogeneity, and workability; and reduce bleeding and efflorescence. In sprayed-on stucco, the addition of diatomite reportedly reduces rebound. Throughout the world, diatomite and clay-bearing diatomite are used as pozzolans. In asphalt products, diatomite can decrease cracking tendencies associated with rapid temperature change, improve cohesive strength, control viscosity, and improve the application characteristics of mastics.

Other Uses

Diatomite filler is used as a processing aid in rubber manufacture, and as a mild abrasive in polishes and cleansers. Fineness, absorptive capability, and low abrasiveness make diatomite powders and granules effective carriers and diluents for use in agrochemicals.

Diatomite provides the source of low density, heat resistance, and porous silica in catalyst carriers such as those used in hydrogenation processes and sulfuric acid manufacture. Similarly, diatomite is used in porous, inert chromatographic supports. Diatomite powders are also used as a silica source for the production of synthetic calcium and magnesium silicates. These unique products exhibit extremely high surface area (105 to 190 m²/g) and are able to absorb up to 5½ times their weight in water. Some commercial synthetic silicates are able to absorb 3 to 4 times their weight in water and remain dry, free-flowing powders. In some parts of the world, diatomite is formed directly into insulating brick.

Other miscellaneous applications include use in match head and welding rod composition, as an anticaking agent on ammonium-nitrate prills, as a stabilizer in explosives, and as a silica source for calcium silicate filler for acetylene cylinders.

Product Pricing

Based on statistics compiled by the USGS and the U.S. Bureau of Mines, the weighted average price of diatomite per metric ton sold or used by U.S. producers rose from \$219 in 1990 to \$258 in 2003, reaching a peak of \$271 in 2001 (Table 2). The USGS reported that the average price per ton for most end uses in 2002 and 2003 decreased from that of 2001.

Competitive Substitutes

Many minerals and materials are used in filtration applications in which a porous filter bed is used to mechanically remove suspended solids from a liquid. In addition to diatomite, other commonly used materials include expanded and milled perlite, sand, garnet, asbestos, cellulose, and carbon. Although diatomite is acknowledged as a superior performer for a broad range of commercial and municipal filtration problems, each of the other materials can be suitable for specific or niche applications and can exhibit advantages in terms of effectiveness, cost, durability, and availability. In the last decade, the use of ultrafiltration and synthetic membranes has become more widespread. The performance and suitability of alternative filtration systems, however, must be considered in terms of the specific application. The filtration system installation and operational costs of common membrane filtration units must be taken into account, because they are more expensive than typical diatomite systems (Crossley 2000).

Talc, silica sand, ground mica, clay, expanded and milled perlite, and ground calcite are a few of the many mineral fillers sold into the large and diverse filler markets in addition to diatomite.

Chemically modified or synthetic fillers represent a second important group of fillers. Selection of appropriate fillers is based on cost, availability, and performance. The physical properties of diatomite make it useful as a functional filler in a broad spectrum of industrial applications. Although substitute fillers may be used, replacement may require that the final product be reformulated.

Minerals that can compete with diatomite as absorbents include sepiolite, attapulgite, and bentonite, among others. Although these minerals share some market applications, each has its various niches.

Packaging

Powdered diatomite products are sold in both 22.68-kg (50-lb) bags and in bulk form. In the United States, powdered diatomite is primarily sold in 50-lb bags, although it is also available in 800- and 1,000-lb sacks and in bulk form via pressure differential railcars and trucks. Bagged products are palletized and can be stretch- or shrink-wrapped for shipment. In Europe, powdered diatomite has been sold in 20-kg bags and in 1,000- to 2,000-L sacks.

Bags are labeled with the product and trade name and can be labeled with a customer's specific in-house identification if requested. Labels may also be placed on the shrink wrap that covers palletized loads at the customer's request. Caution labels are placed prominently on each bag or on the palletized load advising the product handlers of the health issues associated with the crystalline silica present within diatomite products. Caution advisories may be printed in several languages on each of the labels, and in addition, special labeling may be required for different locations. Great care must be taken to comply with labeling requirements.

Transportation

Freight costs have a significant impact on the overall cost of products to the customer. Diatomite products are bulky because of their low density; as a result, transport cost per ton is high. After palletizing and wrapping, bagged products are transported to distribution centers or directly to customers by truck or by rail and ocean freight in containerized loads. Alternatively, pneumatic railcars and truck tankers are used to transport diatomite powders in bulk directly to the customer's storage bin. In the United States, the majority of products are bagged and shipped by truck in palletized form.

In the United States, products destined for export are typically palletized and transported to port in containers as large as $12.2 \times 2.7 \times 2.7$ m that are easily transferable to ship, truck, or rail systems. The major elements of export contracts that must be routinely negotiated include inland freight obligations at both ends of the transport, marine cargo insurance, and currency and fuel adjustment factors. Tariffs and taxes associated with export are considered separately in the next section.

ECONOMIC OR COMPETITIVE FACTORS

Import Tariffs, Taxes, and Depletion Allowance

Most of the major trading countries now use the international Harmonized Commodity Description and Coding System (HS) to classify products for tax purposes. Under this system, imported natural diatomite products and products calcined without sintering agents are classified under designation 2512 as siliceous fossil meals and similar siliceous earths. This heading includes tripolite, diatomite, and molar earths. Diatomite products that are calcined with the addition of sintering agents such as sodium chloride or sodium carbonate are classified under a separate heading, 3802, as activated products. Bricks, blocks, tiles, or other ceramic goods of siliceous fossil meals are classified under heading 6901. Import duties and other taxes vary throughout the world and are set by the fiscal and customs authorities of each country.

No tariffs are applied to 2512 diatomites and straight calcined diatomites imported into the United States. A duty of 2.5% is imposed on flux calcined diatomite imported in the United States. Products are exported from the United States under general license with no restrictions. Depletion allowance is set at 14%.

Costs and Timing

In the United States, the cost of production can be approximately divided as follows: 10% mining, 60% processing, and 30% packaging and shipping (Benton 1983). Energy is the largest single element of direct cost, representing roughly 30% of the total cost (P. Lenz, personal communication). Freight costs, which are discussed generally here (see the section on Transportation), have a great impact on the cost to the customer.

The cost of and time required for exploration, mine development, and plant development vary widely and depend on the unique requirements of any given project. For example, the cost of building a new plant will be dictated by such factors as the products that are to be made, the need for a kiln, and the production capacity that is required. In general, a greenfield facility capable of manufacturing calcined filter aids and fillers might cost \$20–\$25 million or more. In the United States, bonding is required and such plans must be approved by the U.S. Bureau of Land Management. Individual states manage the plans. In determining the bond amount, health issues, land use and zoning, environmental concerns, and reclamation, closure, and decommission issues are considered. Additional costs may include royalties paid to mineral owners for extraction. The contractual agreements employed for determining royalty payments can vary from mine to mine, but royalty payment is quite commonly calculated as a percentage of the value of the annual sale of finished goods. Minimum annual royalty may also be a feature of individual royalty agreements.

REGULATORY AND ENVIRONMENTAL CONSIDERATIONS

Health and Safety

In the United States, exposure to diatomite is primarily an occupational issue. Prolonged and excessive exposure to respirable crystalline silica dust is a known cause of silicosis (pneumoconiosis). As discussed previously, diatomite can contain crystalline silica species in varying abundance. In 1996 the International Agency for Research on Cancer (IARC) reclassified crystalline silica as a Group 1 known human carcinogen. Crystalline silica is also listed as a human carcinogen by the U.S. National Toxicology Program, and under California Proposition 65, airborne crystalline silica of respirable size is listed as a substance known to the State of California to cause cancer (Anon. 1998; W. Miles and M. Mirliiss, personal communication). IARC has classified amorphous silica as a Group 3 substance, not classifiable as to carcinogenicity.

The diatomite industry has addressed the health issues associated with mining, processing, and handling of crystalline silica dusts for many years. In the United States, worker exposure to such dusts is regulated under the Occupational Safety and Health Administration (OSHA) and by the Mine Safety and Health Administration. Classification as Group 1 triggers the regulation of respirable crystalline silica under the Hazard Communication Standard as administered by OSHA, and producers must appropriately label their diatomite products that contain more than 0.1% of this substance. In addition, health and safety information is provided on material safety data sheets (MSDSs), which include information on the carcinogenicity of respirable crystalline silica.

Manufacturers are responding directly by conducting worker and consumer protection, education, and training programs, and by implementing and maintaining industrial hygiene programs in plants. MSDSs have been and will continue to be revised to meet OSHA requirements.

Because crystalline silica occurs as a principal or minor accessory mineral in most mineral products, the designation of crystalline silica as a carcinogen affects nearly all mineral-related industries. The diatomite industry formed the International Diatomite Producers

Association (IDPA) in 1988 to study and report on the health, safety, and environmental issues related to the industry. In addition to sponsoring health-related research, the IDPA has published educational literature on crystalline silica for workers and users of diatomite products. Information is available through the IDPA (Long Beach, California), and also from the American Chemistry Council (Arlington, Virginia).

The health regulation issues associated with respirable crystalline silica continue to evolve in both the United States and Europe. The European Union does not currently have an occupational exposure level limit for respirable crystalline silica, although one is under consideration by the Scientific Committee on Occupational Exposure Limits, a subcommittee of the European Commission (M. Mirliss, personal communication).

Other Regulatory Issues

In the United States, land use and zoning issues associated with mining, plant construction, and production can be of significant concern depending on the location of the operation and its proximity to sensitive environmental areas and/or to residential and urban development. In general, reclamation requirements are becoming more restrictive and more stringently enforced. Reclamation that is concurrent with mining is commonly employed. Control of fugitive dust emissions has become a key issue as regulations have become increasingly stringent and subject to enforcement.

There are no U.S. federal disposal restrictions, although some states may impose restrictions. Landfill disposal costs for used or spent filter cake have long been of concern to the end user. To avoid such cost, some end users may seek to recycle their waste through secondary usage such as land farming or use in animal feed. Alternatively, some end users have examined the viability of other filtration technologies.

OUTLOOK AND FUTURE TRENDS

United States

From 1980 to 1990, production capacity in the United States for fillers, absorbents, and filter aids increased through the development of five new operations. Following the construction of the new filler and filter aid plants, U.S. overcapacity was estimated to be in excess of 25% (Anon. 1987a, 1989). Since 1990, the industry has experienced a net reduction of domestic production capacity by the closure of the large Grefco mining and manufacturing operations at Lompoc, California, and by the closure of the Oil-Dri facility in Oregon. These capacity decreases have been somewhat offset by the startup of Dia-Source operations in Oregon and by Atlas Minerals Inc.'s intermittent operations during 2002 at Mammoth, Arizona. Even though emerging applications such as natural grade insecticide, biotechnology, and pharmaceuticals continue to develop, no major new market applications that will greatly increase usage have been announced. In general, consumption in the filter aid and absorbent market segments is not expected to grow during the first half of the current decade, whereas modest growth is expected for filler and natural grade insecticide market segments.

The free crystalline silica associated with diatomite persists as an industry concern.

Exploration of deposits has continued throughout the western United States and in the state of Virginia.

The Rest of World

Since 1992, world output was estimated by the USGS to range from 1.93 to 2.02 Mt, and for 2002, it was estimated at 1.95 Mt (Dolley 2002).

During the past decade, attention has focused on the development of Chinese resources at Changbai, Jilin, and on investigation of deposits in Australia, New Zealand, Vietnam, and the former Soviet Union.

ACKNOWLEDGMENTS

Special acknowledgments are given to Peter E. Lenz and to Eagle-Picher Filtration & Minerals, Inc., for their generous support. Grateful acknowledgment is given to Melva Bodycomb; Merrill Fisher; Arlene von Sternberg Breese; William P.S. Breese; and Jim Lauria, president of Filtration & Minerals LLC, for their valuable support. The authors wish to gratefully acknowledge the boundless contributions, help, and enthusiasm of Fred Eric L. Kadey, Jr., a pioneer in diatomite (deceased 2004).

Feldspars

Michael J. Potter

INTRODUCTION

Feldspars make up the most abundant mineral group in the earth's crust. They account for an estimated 60% of the exposed rocks, as well as soils, clays, and other unconsolidated sediments, and are principal components in rock classification schemes.

Feldspars are aluminum silicate minerals that contain varying proportions of calcium, potassium, and/or sodium. The principal feldspar species are albite (sodium feldspar), anorthite (calcium feldspar), and microcline and orthoclase (potassium feldspars). These species are almost never found in pure form in nature but occur as mixtures of varying proportions.

Pegmatites, which are one source of feldspar, are exceptionally coarse-grained igneous rocks and have a composition similar to that of granite. The composition may be simple or complex and may include minerals rich in such elements as lithium, rare earths, tantalum, and others (Jackson 1997). Perthite is a variety of alkali (sodium-potassium) feldspar in which the potassium-rich phase (typically microcline) appears to be the host from which the sodium-rich phase (typically albite) exsolves (i.e., unmixes). The exsolved areas are visible to the naked eye and typically form irregular veinlets, strings, and so forth (Jackson 1997). Antiperthites have sodium-rich plagioclase as the host feldspar and intergrowths of potassium-rich feldspar. What is commonly known as Spruce Pine alaskite is an important feldspar ore-bearing rock that occurs in the Spruce Pine District of North Carolina. This alaskite has been described as a coarse-grained pegmatitic granite (Kaufman and Van Dyk 1994). According to A. Glover (personal communication), a true alaskite has a higher potassium than sodium content, whereas the Spruce Pine alaskite has a higher sodium than potassium content. Alaskite generally contains microcline, orthoclase, and quartz; plagioclase may or may not be present (Rogers, Neal, and Teague 1983). Aplite that was mined in 2003 (in only one U.S. location, in Virginia) is a metanorthosite (metamorphosed anorthosite) with a high proportion of plagioclase feldspar.

Feldspars are widely used in the glass and ceramic industry. Nepheline syenite, which is covered in a separate chapter in this book, is a light-colored, silica-deficient feldspathic rock made up mostly of sodium and potassium feldspars and nepheline. Although not mined in the United States for glass and ceramic use, nepheline syenite has been imported from Canada for a number of years for that use. A single operation in Arkansas has been producing nepheline syenite for its internal use in manufacturing roofing granules and related products.

The first commercial production of feldspar in the United States occurred in about 1825 and was mined from pegmatite bodies located in Connecticut. The feldspar was hand sorted and shipped to England. During the nineteenth and twentieth centuries, feldspar production grew with new production locations, integrated mine and processing facilities, and the development in 1939 of the flotation process for feldspar by the U.S. Bureau of Mines (USBM) and the feldspar industry. The first commercial feldspar flotation plant began operations in Kona, North Carolina, in 1946 (Feitler 1967; Rogers, Neal, and Teague 1983).

In 2003, U.S. production of feldspar, based on reported and estimated data, was about 800,000 t. World production of feldspar, excluding China, was an estimated 10.8 Mt (Potter 2005).

Since 1980, the U.S. feldspar industry has seen some expansion of plant capacity, a few plant closures, and changes in ownership of existing operations. In its glass end-use market, the industry has been affected by glass recycling and by competition from metal, paper, and plastic containers. In ceramics, the other major market for feldspar, much of the manufacturing of plumbing fixtures and tiles is in Brazil, China and other Asian countries, and Western Europe (Roskill Information Services Ltd. 2002). Brazil, China, Colombia, Italy, Mexico, and Spain are significant exporters of plumbing fixtures and tile to the United States (Ceramic Industry 2004; Grahl 2004).

PRODUCTION AND TRADE

North America

U.S. production of feldspar comprises hand-cobbed, flotation concentrates, feldspar-quartz mixtures (feldspathic sand), and aplite. Beginning in 1992, aplite has been included with feldspar production data. Table 1 shows U.S. feldspar production from 1980 to 2003. Flotation concentrates comprised about 70% to 80% of output through 1991 and about 40% to 45% thereafter. Feldspar-silica mixtures and hand-cobbed material made up about 20% to 30% through 1991, and thereafter, with aplite being included, about 55% to 60% of the output.

Feldspar was mined in seven states in 2003, which were, in descending order of output, North Carolina, Virginia, California, Georgia, Oklahoma, Idaho, and South Dakota. North Carolina accounted for about 45% of the total. Ten companies mined feldspar, nine of which operated 12 beneficiation facilities—four in North Carolina, three in California, and one in each of the five remaining states mentioned (Table 2). U.S. production data for feldspar are collected by the U.S. Geological Survey (USGS) by means

Table 1. Feldspar production in the United States, kt

Year	Flotation Concentrate	Percentage	Other*	Percentage	Total
1980	513	80	131	20	644
1985	442	70	193	30	635
1990†	440	70	190	30	630
1995†	400	45	480	55	880
2000†	330	42	460	58	790
2003†	330	41	470	59	800

Source: USBM 1981–1996; USGS 1997–2005.

* Includes hand-cobbed feldspar, feldspar-quartz mixtures (feldspar content), and (beginning in 1992) aplite.

† Data rounded to no more than two significant figures because of partially estimated data.

of a voluntary survey. Of the 12 known beneficiation facilities in 2003, 6 responded with production data by the survey deadline. These 6 facilities represented about 64% of the production shown in Table 1. In 1985, the response rate, by tonnage, was 81%; in 1990, 75%; and in 2000, 60%. As a result, U.S. production data in Table 1 for 1990 and after have been rounded to no more than two significant figures because of partially estimated data.

Canada has had no feldspar production for a number of years, although some projects are being developed. Avalon Ventures Ltd. of Toronto, Ontario, continues work on its Warren Township, Ontario, anorthosite (calcium plagioclase feldspar) project. Also under development is the company's Separation Rapids project near Kenora, Ontario, which has a deposit containing high-lithium feldspar, for potential use in glass and ceramic manufacture (Avalon Ventures Ltd. 2004). Another company, i-minerals inc. of Vancouver, British Columbia, continues to test and develop two feldspar deposits at its Helmer-Bovill property in Latah County, Idaho. Its Kelly's Basin deposit contains sodium feldspar, and the "WBL" tailings (previously owned by Washington Brick and Lime Co.) contain potassium feldspar and quartz (i-minerals inc. 2004).

U.S. imports of feldspar increased from 864 t in 1985 to a high of 17,900 t in 1991. Between 1999 and 2003, imports fluctuated between about 5,500 tpy and 8,000 tpy. Most of the imported material from 1986 to 2002 came from Mexico. Beginning in 2003, Turkey became a significant exporter of feldspar to the United States (Table 3). U.S. feldspar trade and apparent consumption statistics are shown in Table 4.

Production of feldspar in Mexico increased from 163,000 t in 1990 to an estimated 330,000 t in 2003. Mexican exports between 1997 and 2003 fluctuated between about 5,900 tpy and 11,400 tpy, with 98% to 99% going to the United States. Mexican imports of feldspar between 1997 and 2003 were between 1,200 tpy and 5,150 tpy. The United States supplied between 86% and 98% of the total (U.N. Statistics Division 2004).

Rest of World

Feldspar is produced in more than 50 countries. According to preliminary data and estimates by the USGS for 2003, the following countries produced these estimated amounts of feldspathic materials:

- Italy—2.5 Mt
- Turkey—1.8 Mt
- France—650,000 t
- Germany—450,000 t
- Spain—450,000 t
- Czech Republic—350,000 t
- Egypt—350,000 t

Significant production also has come from China and countries in Southeast Asia. Table 5 shows exports from selected countries.

In Italy, output in 2002 included a plite, feldspathic sand, sodium feldspar, sodium-magnesium feldspar, and sodium-potassium feldspar. Gruppo Minerali SpA and Maffei SpA are among the largest producers. Aplite mined by Maffei contains sodium feldspar (20%), potassium feldspar (40%), quartz (30%), and other minerals (10%). End uses for feldspathic products include floor and wall tile, glass, sanitary ware, and tableware. A major development in recent years has been gres porcellanato (i.e., glazed and unglazed porcelain tiles), which contain a high percentage of feldspar. Most Italian feldspar production is consumed domestically, and large quantities of the mineral are imported for the ceramics industry. Italian imports of feldspar increased from 246,000 t in 1992 to 1,865,000 t in 2001 and about 2,290,000 t in 2003 (U.N. Statistics Division 2004; 2003 data given in Table 6). Most of the imported material came from Turkey (Roskill Information Services Ltd. 2002; Crossley 2003; U.N. Statistics Division 2004).

In Turkey, the majority of feldspar produced in 2003 was albite, although potassium feldspar had a small output. There were six main and six smaller producers. Two of the large companies, Çine Akmaden Madencilik Tic. A.Ş. and Esan Eczacıbaşı Endüstriyel Hammaddeler San. ve Tic. A.Ş., produced flotation feldspar. A third company, Kallitun Madencilik San. ve Tic. A.Ş. had plans for a new flotation plant in the works in 2003. Flotation feldspar, with its increased whiteness, was being consumed by porcelain tile producers in Italy and other countries (Crossley 2003).

Turkish exports of feldspar grew from 163,000 t in 1991 to 2.1 Mt in 2000. The main reason for the rapid increase in shipments was a sharp rise in demand from ceramics companies in Italy and Spain (Roskill Information Services Ltd. 2002). Turkish exports were reported to be around 2.2 Mt in both 2001 and 2002 and about 3 Mt in 2003. About 90% of the exports in 2003 went to Italy and Spain (Crossley 2003; U.N. Statistics Division 2004).

In Asia, sodium feldspar is probably the most widely used feldspar because of its relative abundance, especially in China and Thailand, both of which are major exporters (Lines 2003). Although official data are not available, Chinese production of feldspar may exceed 2 Mtpy (Roskill Information Services 2002). Estimated production in 2003 for Thailand was 780,000 t and for the Republic of Korea, 400,000 t. Japan produced an estimated 50,000 t of feldspar in 2003 and an estimated 300,000 t or more of aplite (Potter 2005). Table 7 shows feldspar production for a number of selected countries.

Chinese exports of feldspar in 2001 were 557,000 t, with at least 400,000 t probably being exported to Taiwan, some of which was shipped via Hong Kong. In 2003, Chinese exports were about 600,000 t, with major destinations of Indonesia, Japan, Malaysia, the Republic of Korea, Taiwan, and Vietnam. In 2001, exports of feldspar from Thailand were reported to be about 330,000 t, with about 200,000 t going to Malaysia. In 2003, Thai exports were again about 330,000 t, with major destinations of Malaysia, United Arab Emirates, and Vietnam (Roskill Information Services Ltd. 2002; U.N. Statistics Division 2004).

Potentially economic deposits of feldspar occur in at least 70 countries, and the potential supply throughout the world is presumed to be large. Feldspar reserve and resource data have only been assessed for a few countries: Reserves in Brazil have been estimated at 23 Mt; in Italy, 14 Mt; and in the Republic of Korea, 36 Mt. Detailed estimates of world reserves and resources for most countries are not available or have not been compiled (Roskill Information Services Ltd. 2002).

GEOLOGY

The common feldspar minerals can be represented in a ternary phase system that shows feldspar mineralogy; the end members are KAlSi_3O_8 (orthoclase), $\text{NaAlSi}_3\text{O}_8$ (albite), and $\text{CaAl}_2\text{Si}_2\text{O}_8$ (anorthite). The end-member compositions also are referred to as potassium, sodium, and calcium feldspar (Table 8). The feldspars whose chemistry ranges between the potassium and sodium end members are known as alkali feldspars, whereas those between the alkali and calcium end members are plagioclase feldspars. The plagioclase series is arbitrarily subdivided and named according to increasing mole fraction of the anorthite component: albite, oligoclase, andesine, labradorite, bytownite, and anorthite (Jackson 1997). The feldspar groups can be further subdivided based on structural and compositional features within the alkali or plagioclase feldspar series (Kauffman and Van Dyk 1994). The feldspars have become the primary tool in the classification of igneous rocks (Deer, Howie, and Zussman 2001). Table 8 gives theoretical end-member compositions of the principal feldspars.

Minerals of the feldspar series have some similar physical properties: a Mohs hardness of 6, a specific gravity range of 2.54 to 2.76, and a vitreous luster. Color can range from colorless, white to gray, green, yellow, and red; feldspars may be translucent to transparent.

Geologic Occurrence and Major Deposits

The major U.S. commercial feldspar deposits in 2003 were Spruce Pine alaskite; the aplite in Hanover County, Virginia; pegmatites; and various sand deposits, including certain beach, dune, and river sands, derived from granitic source rocks.

Alaskite

Spruce Pine alaskite is a granitic rock that is composed principally of plagioclase, quartz, orthoclase, and muscovite, in decreasing order of abundance (Feitler 1967). Mined only in North Carolina, it is a major source of feldspar production in the United States. Alaskite occurs in three principal areas, referred to as the Spruce Pine, Penland, and Crabtree alaskite bodies, which are located, respectively, in Mitchell, Avery, and Yancey counties, North Carolina (Olson 1944). The largest mass of alaskite is between Spruce Pine and Chalk Mountain in Mitchell County. A 1981 mineral analysis of Spruce Pine alaskite showed 42.9% sodium (sodic plagioclase) feldspar, 28% quartz, 14.7% potassium feldspar (microcline, generally perthitic), 7.5% muscovite, 6.4% calcium feldspar, and small amounts of iron minerals and garnet. A corresponding average chemical composition of alaskite was SiO_2 , 74.4%; Al_2O_3 , 15.4%; Fe_2O_3 , 0.4%; CaO , 0.9%; K_2O , 3.4%; Na_2O , 5.1%; and LOI (loss on ignition), 0.4% (Redeker 1981). A 2004 analysis of Spruce Pine alaskite generally had the following mineral composition: 35% sodium feldspar (sodic plagioclase), 25% quartz, 30% potassium feldspar, 6% muscovite, and 4% calcium feldspar (A. Glover, personal communication).

For comparison, an average chemical composition for granite was given as SiO_2 , 70.2%; Al_2O_3 , 14.5%; Fe_2O_3 , 1.6%; FeO , 1.8%; CaO , 2.0%; K_2O , 4.1%; Na_2O , 3.5%; and small amounts of other components (Reed 2004).

Historically, in this region of North Carolina, pegmatites containing large amounts of microcline are thick (about 8 to 46 m) and occur near the abundant alaskite extending along the southeast side of the district from near Ingalls through Spruce Pine to the Crabtree Creek area. Prior to 1940, all the feldspar was mined from pegmatites by hand, but since 1940, the commercial production of feldspar has been revolutionized by feldspar flotation. Alaskite

Table 8. Theoretical end-member compositions of the principal feldspars, %

Type	K_2O	Na_2O	CaO	Al_2O_3	SiO_2
Microcline	16.9	0	0	18.4	64.7
Orthoclase	16.9	0	0	18.4	64.7
Albite	0	11.8	0	19.4	68.8
Anorthite	0	0	20.1	36.6	43.3

replaced pegmatites as a source of raw material because bodies of alaskite are larger than the pegmatites. Also, compositional and mineralogical uniformity are greater, making the alaskite a more desirable flotation feed (Brobst 1962).

Aplite

Aplite is defined as a light-colored igneous rock consisting essentially of quartz, potassium feldspar, and sodic plagioclase (Jackson 1997). Commercial aplite mined near the Piney River area in Virginia until 1980 was identified previously as a pegmatite, a syenite, and Roseland anorthosite (Brown 1962). A description of rock from the same locality (Castle and Gillson 1960) suggests that the rock originally contained very coarse feldspar, which was subsequently granulated to give it a marked variability in texture. Aplite mined from Hanover County, Virginia, is the one current (2003) source of commercial production. The deposit is part of the Montpelier metanorthosite where rock is mined by U.S. Silica Co. (formerly by The Feldspar Corp.) at a quarry near Montpelier, Virginia (Bice and Clement 1982; Clement and Bice 1982). The metanorthosite intruded the Sabot gneiss and consists of two phases: a coarse-grained, gray, nonfoliated phase and a granulated, medium-grained foliated phase. The coarse-grained phase contains plagioclase crystals up to 25 to 35 cm that constitute 85% to 90% of the total rock.

Feldspar-Quartz Mixtures (Sands)

Feldspar is an abundant constituent in modern sands of diverse origins (Pettijohn, Potter, and Siever 1973). These sands most commonly occur as beach sands, sand dunes, and river sands. River sands tend toward more feldspathic compositions than either dune or beach sands. Although relatively few petrographic analyses give a breakdown of feldspar varieties, a survey of those that do suggests that potassium feldspar (orthoclase, microcline) is most abundant, followed by sodium plagioclases and the calcium plagioclases.

Feldspar-quartz mixtures currently make up part of the current feldspar market and have been a significant portion of the industry. A major part of this production comes from the feldspar-rich quartz sand deposits located in California, Idaho, and Oklahoma. Some feldspar-quartz mixtures are a coproduct from feldspar flotation operations.

The primary active California deposits are sandstone and deltaic deposits that contain quartz, and a range of 10% to 35% contained feldspar (Silva 1985). The Idaho deposit is a lacustrine (derived from a lake bed) sand with an estimated feldspar content of 30%. The Oklahoma operation processes an Arkansas River sand deposit containing 25% feldspar, of which about 72% is potassium feldspar (Bowditch 1978). In most cases, these silica deposits have been identified as extensive.

Although they have not been developed thus far, the Kankakee dune sands in Kankakee County, Illinois, contain an average of about 21% feldspar. The sands are composed of quartz, plagioclase feldspars, potassium feldspar, mica, pyrite, and some other accessory minerals (Bhagwat et al. 2001).

Granite

Granite is a plutonic (igneous) rock that contains largely feldspar and quartz and in which the alkali feldspar/total feldspar ratio generally is restricted to the range of 65% to 90% (Jackson 1997). Granite is mined from only one state: Georgia has two granitic sources, which have been mined for feldspar for a number of years. The Shadydale granite, mined in Jasper County, has a chemical composition of 13.9% Al_2O_3 , 0.9% CaO , 3.6% K_2O , and 4.7% Na_2O . The Siloam granite, mined in Greene County since 1980, is a porphyritic granite containing perthitic microcline—47% microcline, 25% plagioclase, 20% quartz, 3% perthite, and 5% biotite. Ore from the two mines is blended and processed in a plant to produce a potassium-grade feldspar.

Pegmatites

Exceptionally coarse-grained igneous rocks, pegmatites have a composition similar to that of granite (Jackson 1997). Granitic pegmatites, widely distributed throughout the crystalline rock areas of the United States, occur in rocks of many geologic ages and are most abundant near the margins of granitic intrusions. Most of the important pegmatite districts are included in three broad geographic belts:

- Appalachian Belt, which extends from Alabama to Maine
- Rocky Mountain Belt, which encompasses Colorado, Idaho, Montana, New Mexico, South Dakota, Texas, Utah, and Wyoming
- Western Belt, which covers Arizona, California, Nevada, Oregon, and Washington

From about 1865 to 1991, pegmatites in the Middletown, Connecticut, area were mined almost continuously for feldspar and other minerals. Pegmatite occurrences in the Middletown Area have been recorded in the hundreds. These pegmatites are composed essentially of perthite, quartz, plagioclase, and muscovite. Approximately 42% of the pegmatites contain more than 40% plagioclase. The Middletown pegmatites are largely granitic in composition and form a vast resource of feldspar, quartz, and scrap mica. The relative abundance of potassium and sodium feldspar-rich pegmatites is not related to the formation in which the pegmatite occurs, but rather shows a regional pattern in which potassium feldspar-rich pegmatites are more numerous to the south (Stugard 1958).

North Carolina pegmatites are located in the Kings Mountain Belt within the Shelby District covering Cleveland, southwestern Lincoln, and western Gaston counties. The area currently has one producing operation (Bundy and Carpenter 1969); the feldspar that is obtained is a by-product of mica production (in 2003 as a feldspar-quartz mixture). At the south end of the district, a coarse-grained phase of the Cherryville quartz monzonite is mined for mica, feldspar, quartz, and kaolin. The coarse-grained granite is gradational into pegmatite and also is cut by pegmatite dikes. Depending on weathering, the total feldspar content ranges from 13% to 40%, and the potassium feldspar content ranges from 6% to 7% (Horton 1981). Lithium pegmatites are located northwest of Kings Mountain and the Bessemer City area and were mined until 1998. The average composition of the lithium pegmatites going to mill feed was 20% spodumene, 32% quartz, 27% albite, 14% microcline, 6% muscovite, and 1% trace minerals. The pegmatites are generally not zoned, and the fairly uniform grade of the crude ore allows recovery of feldspar and mica by-products (Kesler 1976). Feldspathic sand was recovered as a by-product from lithium production until 1998, when the last spodumene mine was closed.

The pegmatites of the Black Hills, South Dakota, occur in two main areas. The Harney Peak area encompasses the Keystone Dis-

trict in Pennington and Custer counties, the Hill City District in Pennington County, and the Custer District in Custer County. The second area is the Tinton District in Lawrence County. Although the greater part of the pegmatite-bearing area is in Custer County, the Keystone District has a record of significant mineral production from pegmatites. The most abundant minerals of the South Dakota pegmatites are plagioclase feldspars (oligoclase and albite), potassium feldspars (perthite and microcline), and quartz. The minerals are uniformly distributed in many pegmatites, but in others they tend to be concentrated in specific structural units. South Dakota pegmatites have been classified on the basis of mineral distribution, texture, and their structural relationships to the wall rocks (Page 1953; Norton 1964).

The following gives detailed descriptions of other feldspar occurrences:

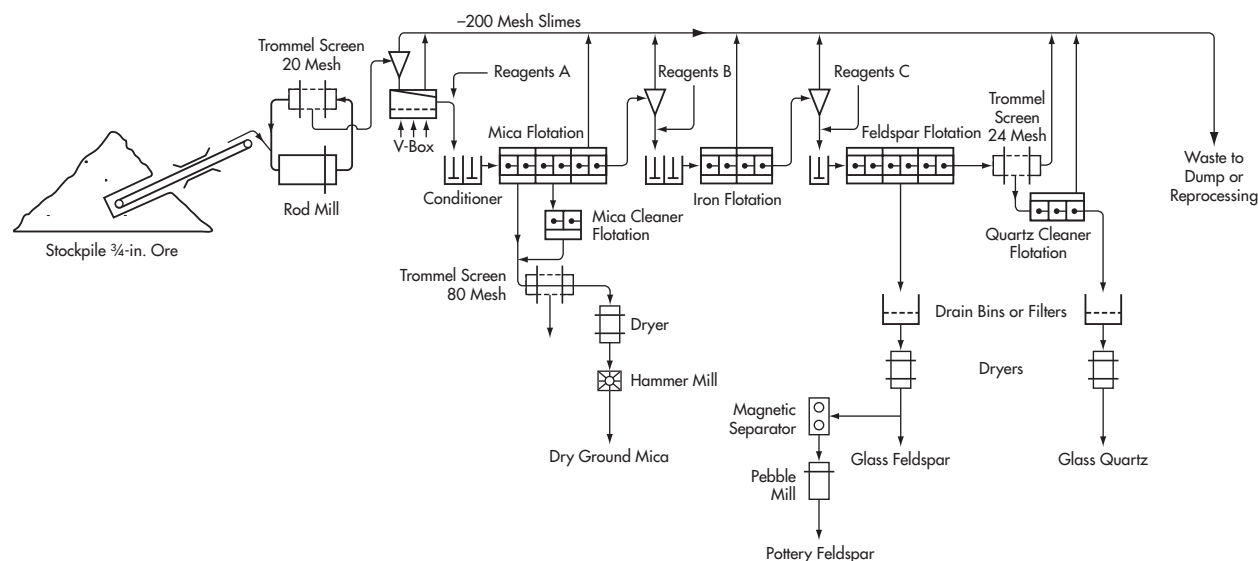

- Barium feldspars have mineral structures very similar to those of potassium feldspars but are rather rare and are not being mined commercially. Barium feldspar with more than 90% of the $\text{BaAl}_2\text{Si}_2\text{O}_8$ molecule is described as celestian (Deer, Howie, and Zussman 2001). Occurrences of barium feldspar have been reported in Australia, Italy, Japan, Namibia, Sweden, Wales, the United States, and a few other countries (Mineralogy Database 2005).
- Amazonite is a gem variety of microcline feldspar and often is polished as a cabochon (i.e., cut so the top of the gemstone forms a convex surface). It displays a Schiller of light, which is a lustrous reflection, also known as iridescence. Amazonite is usually light green to blue green and is found in Australia, Brazil, Namibia, Russia, the United States, and Zimbabwe (Bernardine Fine Art Jewelry 2004).
- Labradorite is plagioclase feldspar. Although much of the stone is dark gray, a Schiller effect can produce blue, green, gold, and yellow iridescent colors. Slabs of labradorite rocks are available in very large sizes, suitable for facings of office buildings. The material also is cut into cabochons. Labradorite is found in Australia, Finland, Labrador, Madagascar, the United States, and other countries (Arem 1987).
- Moonstone refers to a feldspar of widely varying composition and from a wide variety of localities. For example, moonstone from Burma and Sri Lanka displays a white to blue sheen.
- Sunstone is oligoclase or labradorite that contains hematite (Fe_2O_3) or goethite ($\text{Fe}_2\text{O}_3 \cdot \text{H}_2\text{O}$) and inclusions of silicate or clay minerals, which reflect light and create a sparkling sheen in gold to brown color shades. Sunstone is found in Australia, Canada, India, Norway, Russia, and the United States (Arem 1987).

TECHNOLOGY

Commercial feldspar mining in the United States includes mining of feldspathic sand deposits and of hard-rock material such as alaskite. Dredging of river sand occurs at one operation in Oklahoma. In general, after mining of sand deposits or dredging of sand, processing steps can include washing, screening, classifying, leaching to remove surface stains, flotation, and drying. The Spruce Pine alaskite has been a major ore source since the mid-1940s, and a description of a typical alaskite feldspar operation that employs differential froth flotation for the recovery of a pure feldspar product follows.

Mining

Hard-rock mining is done by open-pit methods, either by the mine owner or by contractors. Stripping ratios are nominal, less than 1:1.

Courtesy of Minerals Research Laboratory, North Carolina State University.

Figure 1. Typical flowsheet for feldspar production with alaskite ore

After the feldspar ore is drilled and blasted, secondary breakage is with a conventional drop ball. Ore is then loaded with a hydraulic shovel onto trucks and hauled to the crushing plant, which is adjacent to the flotation plant.

Processing

Figure 1 is a simplified flowsheet of a typical feldspar flotation plant and is intended to acquaint the reader with the concepts involved in feldspar production. Primary crushing is done with a jaw crusher in open circuit. Secondary crushing is with a standard or shorthead gyratory crusher in two or three stages, sometimes in closed circuit with a screen. The final crushed product is -25 m (-1 in.).

Grinding is normally done with rod mills in order to minimize slime generation, although one company uses ball mills without any apparent ill effects. The grinding mills are normally operated in closed circuit with a classifier in order to maximize grinding capacity. Although the feldspar mineral grains are liberated at $850\text{ }\mu\text{m}$ (20 mesh) or larger, grinding is usually carried out to $-600\text{ }\mu\text{m}$ (-30 mesh) in order to optimize the efficiency of subsequent flotation steps. To reduce reagent consumption and produce a higher grade product, the feed to flotation must be sized to eliminate the slimes or $-38\text{ }\mu\text{m}$ (-400 mesh) material. The fact that container glass customers prefer a $+75\text{ }\mu\text{m}$ ($+200\text{ mesh}$) product is also a factor. Desliming is normally done with hydrocyclones.

Once the feldspar feed is properly sized, the differential flotation process can begin. All the unit operations after crushing are operated in a continuous circuit, 24 hours a day, 5 days per week. The first flotation step is to remove mica, which later can be sold as a coproduct. Mica flotation is achieved by conditioning with a cationic collector (an amine) at pH 3 using sulfuric acid. The mica is removed in a froth product and is usually cleaned once prior to being dewatered and sold. Iron-bearing minerals such as garnet and ilmenite are removed next, this time using an anionic collector, petroleum sulfonate, again at pH 3. The iron-bearing minerals are collected in the froth product and pumped to tailings.

The previous unit operations of grinding, sizing, mica flotation, and iron flotation have produced an essentially pure mixture of feldspar and quartz. Some of the traditional feldspar producers are marketing or have marketed this mixture for ceramic use under various trade names such as Min silspar and Silospar. The product is filtered, dried, and cleaned with high-intensity magnetic separation or dry ground and sold, usually in bulk. Other company products are shown in Table 2.

The production of a high-grade feldspar product requires a third flotation step, again at pH 3. The collector is the same cationic amine as used in mica flotation, but this time the pH is controlled with hydrofluoric acid to depress the quartz. The fluorine ion is a powerful depressant in the quartz-feldspar separation. A feldspar product is produced with good recovery in a single rougher flotation step. The feldspar-containing froth product is filtered, dried, and, if necessary, cleaned with high-intensity magnetic separation and stored in bulk prior to sales.

A particular plant generally will produce several different products, all with the same chemistry (because of the same source rock), but with different physical specifications. For ground feldspar for ceramic and filler use, the dried flotation product is ground in a ceramic-lined ball mill in closed circuit with air classifiers to produce a $-74\text{ }\mu\text{m}$ (-200-mesh) or a $-44\text{ }\mu\text{m}$ (-325-mesh) product. As can be seen in Figure 2, this step is one of the more expensive unit operations in the whole processing scheme, and the ground feldspar commands a higher price.

While feldspar producers strive to sell as high a percentage of the ore as possible, tailings (i.e., waste residue left from the processing of feldspar ore) inevitably account for 30% to 40% of the head feed. Tailings are dewatered in settling ponds, by filtration, or in tailings plants. Solid material generally is sent to a landfill, although some could be used as fill material in, for example, mine excavations (A. Glover, personal communication). Figure 2 shows the relative costs of the various unit operations as compared to the total cost of producing feldspar. The data have been derived by using cost experience for the various unit operations and costs that

have been published in cost-estimating manuals (Kaufman and Van Dyk 1994; A. Glover, personal communication).

MARKETING

Uses

In the United States, feldspar for glass manufacturing is usually ground to 850 μm (20 mesh) to 425 μm (40 mesh) and contains 4% to 6% K_2O ; 5% to 7% Na_2O ; approximately 19% Al_2O_3 ; and 0.08% Fe_2O_3 . Pottery-grade feldspar for white ware and similar ceramic products usually ranges from 5% to 14% in K_2O and is ground to 75 μm (200 mesh) with Fe_2O_3 content in the 0.07% range (Potter 1993).

Table 9 shows the consumption of feldspar by major end-use markets from 1980 to 2003. Until 1991, glass (including containers, fiberglass, and other glass) accounted for more than half of consumption. Beginning in 1992, aplite was included in U.S. feldspar statistics, and, because aplite is largely used for glass, glass increased to about 65% to 70% of consumption. Ceramic and other uses were about 40% to 45% of feldspar consumption until 1991 and then decreased to about 30% to 35% thereafter.

Glass

Glass manufacturing is complex and encompasses an enormous range of compositions and product types. Materials for glassmak-

ing can be classified in three groups: glass formers, fluxes, and stabilizers. Glass formers are basic ingredients that can be melted and cooled into a glass, such as silica (quartz sand) (Elert 2005). Fluxes are oxides, including potassium oxide (K_2O) and sodium oxide (Na_2O), which are added to lower the melting temperature of a glass batch. Stabilizers, which can be oxides such as alumina (Al_2O_3) and calcium oxide, impart to the glass a high degree of resistance to physical and chemical attacks. In conjunction, the fluxes and stabilizers control the working characteristics of the glass-forming (Tooley 1984).

Although alumina does not represent a large part of the composition of most glass, it is important because it increases the resistance of glass to chemical corrosion, improves the hardness and durability, and enhances the working characteristics of the glass (Pincus and Davies 1983).

Feldspar provides both alkaline oxides (K_2O and Na_2O) for fluxing and alumina and calcium oxide as stabilizers. An important source of alumina for glassmaking, feldspar has a low iron and refractory mineral content, a low cost per unit of alumina, no volatile constituents, and no waste. The products usually melt between 1,100° and 1,200°C and dissolve readily in the glassmaking batch. A typical batch for container glass contains about 8% feldspar, and a batch for glass fiber insulation contains about 18% (Roskill Information Services Ltd. 2002).

The consumption and selection of glass raw materials are influenced significantly by the economics of the glass-manufacturing process and the glass product market. Therefore, specifications for raw materials vary based on particular circumstances and economics. However, raw materials for the glass industry require rigid physical and chemical specifications.

Ceramics

Ceramic and pottery products are the second largest consumer of feldspar products in the United States. The ceramic products generally consist of ceramic glazes, ceramic tile, dinnerware, electrical porcelain, and sanitary ware.

Feldspars are used in the fine ceramic industry as a flux to form a glassy phase in bodies, thus promoting vitrification and translucency. They also are used as a source of alkalis and alumina in glazes. Feldspars also provide one of the few sources of water-insoluble alkali compounds (Norton 1970).

Consumption of feldspar varies depending on the finished product. Dinnerware and various china products may contain 17% to 20% feldspar; floor tile, 55% to 60%; high-tension electrical porcelains, 25% to 35%; kitchen and ovenware, 10%; vitrified plumbing fixtures, 25%; wall tile, 0% to 11%; and other special ceramic products, including dental porcelain, may require 60% to 80% feldspar (Singer and Singer 1963).

The selection of a potassium versus a sodium feldspar for ceramic applications has been the subject of many investigations (Norton 1970). Feldspar fluxing differences also have been studied (Weinstein 1985) for deformation and the effect of the alkali type in feldspars on the glassy phase formed.

Fillers

Feldspar use as a functional filler and extender in the paint, plastic, rubber, and sealants industries has evolved in recent times as an application that improves product performance. In these uses, feldspar competes with other minerals and nepheline syenite and requires increased levels of research and technical marketing efforts. Feldspar products developed for these markets must comply with the following specifications: dry brightness, oil absorption, Hegman grind, particle-size distribution, surface area, and bulk density.

Feldspar gives paints and coatings favorable properties such as low vehicle demand, which means that the feldspar is not demanding or taking up polymer (binder) out of the paint mixture. Other opportune characteristics of feldspar are low viscosity at high pigment loading; high dry brightness and low tint strength; good film integrity; resistance to abrasion, chemical attack, and chalking (the formation of an easily crumbled powder on the surface of a paint film); excellent tint retention; and ease of dispersal. Compared to nepheline syenite, feldspar has exceptional resistance to frosting (whitening of a painted surface) but may exhibit slightly greater health hazards owing to the presence of free crystalline silica (Mommensen 1988; S. Robinson, personal communication).

Product Pricing

Published prices for feldspar can vary according to the application, particle size, quality, quantity purchased, source, and type of material. Therefore, price quotations serve only as a general guide. From 2000 to 2003, U.S. sodium feldspar prices have shown little or no increase. During the same time period, prices for potassium feldspar increased by about 10% to 30%.

Published prices for U.S. ceramic-grade feldspar at year-end 2003, ex-works (i.e., cost, not including insurance or transport cost), bulk (not in bags), per metric ton, were about \$66 to \$83 for sodium feldspar and \$138 for potassium feldspar. For glass-grade feldspar, prices were about \$44 to \$57 for sodium feldspar and \$94 to \$99 for potassium feldspar. Prices for Turkish sodium feldspar, f.o.b. Gulluk (i.e., free on board at Gulluk port), per metric ton, were \$13 to \$14 for crude, -10 mm, bulk; \$75 to \$80 for ground, -63 µm, bagged; and \$54 to \$56 for glass grade, -500 µm, bagged (*Industrial Minerals* 2003).

Transportation

Feldspar is shipped either in bulk or in 50-lb (23-kg) or larger bags. In the feldspathic minerals industry, the cost of transportation is often equal to the value of the material transported. In 2002, rail transport was still the dominant form of shipping. Rates generally were increasing 2.5% to 3% per year, and fuel surcharges were an additional 2% to 3%. With faster delivery and reasonable costs, truck transport was gaining market share (Rogers 2002).

REGULATORY AND ENVIRONMENTAL CONSIDERATIONS

In the United States, because of its crystalline silica (quartz) content, feldspar falls under the Occupational Safety and Health Administration's Hazard Communication Standards, 29 CFR Section 1900.1200. The standard requires labeling and other forms of warning, material safety data sheets, and employee training for products containing identified carcinogens with concentrations greater than 0.1%.

OUTLOOK

The container glass industry, a major end user of feldspar, continues to face strong competition from other forms of packaging, such as metal, paper, and plastic containers. Use of recycled glass containers (as cullet) in glassmaking decreases consumption of mineral raw materials, including feldspar. Government legislation and regulation are also providing momentum for increased use of recycled glass (Roskill Information Services Ltd. 2002). With escalating production costs and resistance to price increases by consumers, feldspar producers will continue to face a challenging business environment for the foreseeable future (Rogers 2002).

Beer and wine packaging is probably the single largest market for container glass in the world. Countries with large beer industries—including Brazil, the Czech Republic, Germany, Japan, Mex-

ico, the Netherlands, Poland, Russia, Spain, the United Kingdom, and the United States—have substantial glass production capacity. In the immediate future, the fastest-growing markets for container glass are projected to be in Asia and Latin America, where countries have fast-growing populations. At present, glass packaging is said to have a cost advantage over aluminum and plastic containers in most of these countries. For example, the Chinese and Indian container-glass markets are potentially very large (Roskill Information Services Ltd. 2002).

The strong U.S. market in 2003 for new home construction and remodeling consumed about 267 million m² of tile. Imports supplied about 78% of this demand with Italy providing 34% and Spain 17%. Consumption of porcelain tile continued to grow, partly because of its durability. Also, demand is increasing for larger-sized tiles, in sizes ranging from about 30 cm × 30 cm (12 in. × 12 in.) to 51 cm × 51 cm (20 in. × 20 in.) (*Ceramic Industry* 2004).

Although U.S. vitreous china sanitary-ware consumption data are not available, U.S. demand is increasingly being filled by imports. In 2004, Mexico and China were the largest U.S. suppliers, providing about 58% of imports. According to The Freedonia Group, Inc., U.S. demand for vitreous plumbing fixtures may remain flat for the next several years. Instead, regions outside the United States, such as Asia, Eastern Europe, and the Middle East, may provide growth opportunities (Grahl 2004; The Freedonia Group 2004).

Demand for ceramic grades of feldspar is projected to remain relatively stronger than demand for glass grades. The main centers of ceramics production are China, Italy, Spain, Latin America, and Southeast Asia. These areas, and Chinese, Italian, and Spanish companies in particular, have been the major consumers of feldspar during the past 20 years and are projected to remain so in the immediate future (Roskill Information Services Ltd. 2002).

ACKNOWLEDGMENT

Much of the material in this chapter was taken from the Feldspars chapter by Roger A. Kauffman and Dean Van Dyk in 1994.

Fluorspar

Robert B. Fulton III and M. Michael Miller

Fluorspar is the commercial name for fluorite, a mineral that is calcium fluoride (CaF_2). The name, derived from the Latin word *fluere* (to flow), refers to its low melting point and its early use in metal-lurgy as a flux. It is the principal industrial source of the element fluorine.

Two other minerals, cryolite and fluorapatite, have significant fluorine content. Cryolite (sodium aluminum fluoride, Na_3AlF_6), is a rare mineral that has been found in commercial quantities in Greenland. It has also been produced as a by-product of tin mining in Brazil. The natural material has been supplanted by synthetic cryolite for its principal industrial use in the manufacture of aluminum. Fluorapatite [$\text{Ca}_5(\text{PO}_4)_3\text{F}$] is a source of phosphate for fertilizer manufacture and contains a small percentage of fluorine. Commercially mined deposits of apatite have varying amounts of fluorine, chlorine, hydroxyl, and carbonate.

HISTORY

Fluorspar was used by the early Greeks and Romans for ornamental purposes such as vases, drinking cups, and tabletops. Various cultures, including the Chinese and the Native Americans, carved ornaments and figurines from large crystals. Its usefulness as a flux was known to Agricola in sixteenth-century Europe.

Fluorspar mining began in England about 1775 and started at various places in the United States between 1820 and 1840. Production grew substantially following the development of basic open-hearth steelmaking, where it was used as a flux. Use was stimulated by growth of the steel, aluminum, chemical, and ceramic industries, particularly during World Wars I and II. Fluorocarbons entered the picture in 1931, although significant production of these compounds did not occur until after World War II. The use of anhydrous hydrogen fluoride (HF) as a catalyst in the manufacture of alkylate for high-octane fuel began in 1942.

Differential flotation for separating fluorspar from galena, sphalerite, and common gangue minerals in the 1930s and the application of heavy media-concentrating methods to the treatment of low-grade ores in the 1940s were outstanding technological advances that facilitated increased production.

Pelletizing and briquetting of flotation concentrates for use in steel furnaces and the development of flotation schemes for beneficiating ores containing abundant dolomite and barite have been major improvements in the industry.

PRODUCTION, RESERVES, AND TRADE

Major producing countries have been China, England, France, Italy, Mexico, Mongolia, South Africa, Spain, Thailand, the United States, and the former USSR. Other smaller producers have included Argentina, Brazil, Canada, Czechoslovakia, Germany, India, Iran, Kenya, Korea, Morocco, Namibia, Tunisia, and Romania. In 2002, the major producing countries (in descending order of production) were China, Mexico, South Africa, Mongolia, Russia, and Spain. The largest exporters were (in descending order) China, Mexico, South Africa, Mongolia, Kenya, Morocco, and Namibia. World production in 2002 was about 4.55 Mt, and world reserves (measured as 100% CaF_2) are estimated at 230 Mt (see Table 1).

Natural phosphate rock contains approximately 3.5% fluorine as a component of the mineral fluorapatite. Silica, in the form of sand or gravel, occurs with the phosphate rock ore. In phosphate rock processing, the fluorine reacts with the silica and volatilizes as silicon tetrafluoride, which hydrolyzes to fluorosilicic acid when the gas is passed through water scrubbers. Currently, most of this acid

is neutralized with lime. In some countries, however, fluorosilicic acid is converted to a aluminum fluoride and also silica fluorides of sodium, potassium, and ammonium. Although numerous attempts have been made to develop processes to produce hydrofluoric acid from phosphate rock in fertilizer manufacturing, no one has, to date, developed a viable and economic method to separate the silica from the fluorine.

The quantity of fluorine present in phosphate rock deposits is enormous. Current U.S. reserves of phosphate rock alone are estimated to be 1.0 Gt, which at 3.5% fluorine would contain 35 Mt of fluorine, equivalent to about 72 Mt of fluor spar. World reserves of phosphate rock are estimated at 18 Gt (Jasinski 2004), which converts to 630 Mt of fluorine and 1.29 Gt of fluor spar equivalent.

With the exception of fluor spar purchased from the U.S. National Defense Stockpile and some synthetic fluor spar recovered as a by-product of uranium processing, petroleum alkylation, and stainless-steel pickling, the bulk of U.S. fluor spar requirements are imported. In 2001, the United States imported 522 kt of fluor spar, and in 2002, imports totaled 494 kt (466 kt of acid grade and 28 kt of metallurgical grade). Table 2 shows the quantity and value of U.S. fluor spar imports by country and grade.

GEOLOGY

Composition and Properties

Theoretically, pure fluorite contains 51.3% calcium and 48.7% fluorine. Substitution of small percentages of cerium and yttrium for calcium has been noted. Inclusions of gases and fluids, such as petroleum and water, and of solid minerals such as pyrite, marcasite, and other sulfides, are common. Rarely, free fluorine is present in some crystals. Commercial fluor spar may contain various amounts of attached and admixed mineral impurities, such as calcite, quartz, barite, celestite, various sulfides, or phosphates.

Fluorite tends to occur in well-formed isometric crystals, forming cubes and octahedrons. It also occurs in both massive and earthy forms, and as crusts or globular aggregates with radial fibrous texture. Crystalline fluor spar exhibits a great range of colors, from colorless to yellow, blue, purple, green, rose, red, bluish

and purplish black, and brown. The colors may occur in alternating bands parallel to crystal faces. Coloration may be altered by exposure to x-rays, heat, ultraviolet light, and pressure. Colors are caused by a variety of factors, including the presence of trace impurities and displaced ions in the lattice. Long exposure to sunlight, such as in mine dumps, frequently results in the fading of the original coloration.

Some varieties fluoresce blue or violet under ultraviolet light or cathode rays. Some specimens phosphoresce when heated or after exposure to sunlight or ultraviolet light, and some forms exhibit triboluminescence.

Fluorite has a hardness of 4, and is the mineral type of that hardness on the Mohs scale. Its normal specific gravity is 3.18 when crystalline but ranges from 3.01 to 3.6 in various forms. The luster is vitreous. The mineral has perfect octahedral cleavage, and octahedrons, made by cleaving off the corners of cubic crystals, often are seen in collections.

Crystalline fluorite has a very low index of refraction ($n = 1.4339$) and low dispersion, is isotropic, and has an unusual ability to transmit ultraviolet light. These are the properties that make it useful as prisms in optical systems and as components of high-quality, special-purpose lenses. Synthetic fluorite has replaced the natural mineral for optical uses.

Modes of Occurrence

Fluorite occurs in a wide variety of geological environments, evidencing deposition under an extended range of physical and chemical conditions. At one extreme, it is present as an accessory mineral in granites and related igneous rocks; at the other extreme, it is sometimes found as crystals in geodes and as botryoidal linings in limestone caves. From an economic standpoint, the most important modes of occurrence of the mineral are

- Fissure veins in igneous, metamorphic, and sedimentary rocks
- Stratiform replacement deposits in carbonate rocks
- Replacements in carbonate rocks along contacts with acid-igneous intrusives
- Stockworks and fillings in shattered zones
- Deposits in association with carbonatite and alkalic rock complexes
- Residual concentrations resulting from the weathering of primary deposits
- Occurrences as recoverable gangue in base metal deposits

Less common modes, although commercially important in some places, include fillings in breccia pipes, fillings in open spaces, and pegmatites. Least common are deposits in lake sediments.

Fissure Veins

Fissure veins, usually along faults or shear zones, are the most readily recognized form in which fluor spar deposits occur. Silica, calcite or other carbonates, iron, lead and zinc sulfides, and barite are the typical associated minerals. In some vein deposits, such as those in the Rosiclare District of southern Illinois, fluorite appears to have replaced a prior vein filling of calcite. Along some veins in carbonate rocks, fluor spar has replaced the wall rock at intersections with favorable beds, providing large minable tonnages. Although vein structures are remarkably persistent, the fluor spar commonly occurs as lenses or ore shoots separated by barren or poorly mineralized portions of the veins. Ore-shoot widths of 0.5 to 10 m and lengths of 60 to 300 m are common, but there is great variation from deposit to deposit. Vein systems may be up to several kilometers in length, and ore may be present to depths of 300 m or more.

below the surface. The CaF_2 content of minable portions of veins normally ranges from 25% to 80%, although grades above 90% occur in limited areas.

Important vein deposits have been developed in China, adding to the world's great vein deposits that include the Osor deposit in northeastern Spain, the Torgola deposit in northern Italy, the Muscadroxiu-Genna Tres Montis vein system in Sardinia, the Hucklow Edge and Longstone Edge-Sallet Hole vein systems in England, the Rosiclare-Goodhope vein system in Illinois, and the El Hammam vein system in Morocco.

Stratiform Deposits

Stratiform, manto, or bedded deposits occur in carbonate rocks. Certain beds are replaced along or adjacent to structural breaks such as joints or faults. This relationship to structural features is very clear in some deposits but obscure in others. Frequently, there is a sandstone, shale, or clay capping. Typically, there is evidence of loss of volume in the replaced zones with attendant development of gentle synclinal structures in overlying strata or of collapse structures, the latter sometimes pipelike in shape. In some districts, no connection is recognized between the mineralization and any igneous activity. In southern Illinois, mafic dikes, offset by the younger mineralized structures, intrude host rocks superjacent to a rift complex (Baxter and Bradbury 1989). Post-dike igneous activity, related to rift reactivation, is invoked as a deep-seated source of fluorine. In other districts, such as the Encantada District in northern Coahuila, Mexico, the presence of rhyolite plugs and sills in the general vicinity of the spar deposits, and the association of spar with rhyolite injections along bedding planes, suggests a more direct association.

Stratiform deposits are known in many parts of the world and are particularly well developed in the Cave-In-Rock District of southern Illinois, in the northern part of the state of Coahuila in Mexico, and in the Ottoshoop (Zeerust) District in the Republic of South Africa. In Illinois, the deposits range from a few centimeters to 6 m thick, are 15 to 150 m wide, and are up to 7 km long. In Coahuila, the individual ore bodies are smaller but relatively more numerous and widespread. In the Ottoshoop District, bedded deposits occur in an area that is 16 km in length and 10 km wide, in a dolomite facies that underlies a prominent chert bed.

In stratiform deposits, textural features, such as sedimentary banding of the parent rock, are commonly preserved. A massive, crystalline ore type, frequently associated with the banded ore, appears to have filled open spaces left from the dissolution of limestone by the ore-bearing solutions or their precursors. Minerals accompanying fluorspar in stratiform deposits include calcite, dolomite, quartz, galena, sphalerite, pyrite, marcasite, barite, and celestite. Calcium fluoride content in minable deposits ranges from 11% upward. A few ore bodies in Illinois yielded direct-shipping, metallurgical-grade fluorspar containing 85% or more calcium fluoride.

Replacement Deposits

Replacement deposits in carbonate rocks are well developed along contacts with intrusive rhyolite bodies in the Rio Verde, San Luis Potosi, and Aguachile districts in Mexico. They include some of the largest and highest grade fluorspar deposits. The fluorspar, not thought to be contact metamorphic in origin, was apparently introduced later by ore solutions that followed conduits along the contact zone and, either massively or selectively along certain beds, replaced the limestone outward from the contact. At Agua Chile, cross sections show ore shoots resembling one side of a Christmas tree.

Stockworks

Fluorspar often occurs as stockworks and fillings in shear and breccia zones. Many occurrences in the American West are of the stockwork type and, though wide, usually have low overall calcium fluoride content and are consequently uneconomic; deposits in the Zuni Mountains of New Mexico and near Jamestown, Colorado, are examples. The Zwartkloof deposit, in the Transvaal Province of South Africa, consists of three vertical breccia zones containing stockworks of fluorite-carbonate veins. The mineralized breccia zones are in an east-west line and developed in felsite. The largest zone is 60 m by 180 m in plan and persists to 900 m below the surface. The fluorspar grade is about 14%. The Buffalo deposit, near Naboomspruit in the Transvaal, consists of a network of fluorspar veinlets that occur in sill-like bodies of fine-grained, pink granite in the coarse, red granite of the Bushveld Complex.

Carbonatite and Alkalic Rock Complexes

Fluorspar is a common mineral in carbonatite and alkalic rock complexes, although rarely in sufficient abundance to be economically recoverable. The Okorusu deposit in Namibia is an economic deposit of this type and consists of a number of bodies of fluorspar in limestones, quartzites, and related rocks that have been intruded and metamorphosed by an alkaline igneous rock complex that includes a nepheline syenite stock. The fluorspar replaces bedded and brecciated limestone, marble, and quartzite, forming large lenticular masses. Apatite, magnetite, and quartz are abundant accessory minerals. At Amba Dongar, India, veins and replacement bodies of fluorspar occur in carbonate rocks that border an eritic carbonatite in trusives. Fluorite is also present in the carbonatite itself at both Okorusu and Amba Dongar.

Residual Deposits

Concentrations of fluorspar in clayey and sandy residuum, from surficial weathering of fluorspar veins and replacement deposits, are, principally, sources of metallurgical spar. This category includes detrital deposits blanketing the apex of veins, as well as deeply weathered upper portions of the veins themselves. Such deposits, extending to depths of 30 m or more, were of major importance in Illinois and Kentucky. Similar deeply weathered ore has been mined in England, Thailand, and the Asturias District of northwestern Spain. Weathered residuum, called kokoman, is mined in the Marico District in South Africa, where it is the result of the weathering of gently dipping replacement bodies.

Gangue Mineral

Fluorspar occurs as a major gangue mineral in lead-zinc veins in many parts of the world, and in some, averaging 10% to 20%, is economically recoverable. Acid-grade fluorspar has been produced on a large scale from lead-zinc mill tailings in the Parral District in Mexico.

Breccia Pipes

Fluorite occurs in breccia pipes in the Thomas Range in Utah, and near Beatty, Nevada. Pipes in the Thomas Range are circular to oval in plan, up to 45 m in diameter and more than 60 m in depth. They formed in dolomite by replacement along shattered zones associated with faults and intrusive breccias. The fluorspar occurs as soft, friable masses and in boxworks of fine-grained, more resistant veinlets, and is nearly unrecognizable. At the former Daisy mine near Beatty, fluorspar replaces brecciated dolomite in pipe-like bodies bounded by gouge zones along two sets of intersecting faults.

Fillings in Open Spaces

Fluorspar occasionally partially fills open spaces, both in veins and stratiform deposits. Spectacular examples of this type occur in the San Vicente District of northern Coahuila, Mexico, where fluorspar occurs in veins and mantos as pure massive incrustations of mamillary, stalactitic, and stalagmitic forms. The Fluorspar-Gero-Pember vein system of the Northgate mine in Colorado is a similar occurrence where fluorspar occurs in botryoidal layers on the walls of open fissures and as concretionary coatings surrounding loose fragments of country rock. The lower parts of open areas of these fissures are partly filled with concretionary pebblelike masses, in places cemented into porous, rubbly aggregates.

Pegmatites

Many pegmatites contain minor amounts of fluorspar. Grade in three ore bodies was high enough to once support a mining operation at the Crystal Mountain occurrence in Montana. These large, tabular bodies of massive fluorspar, which occur in coarse-grained biotite granite, also contained minor amounts of biotite, quartz, feldspar, and other igneous-type accessory minerals. This deposit is of particular interest because of the presence of scandium.

Lake Sediments

Fluorspar occurs in unconsolidated clayey and sandy pyroclastic sediments in the beds of former lakes near Castel Giuliano, about 40 km north of Rome, Italy. Fluorine of volcanic origin permeated the lake sediments, resulting in deposition of minute disseminated crystals of fluorspar, which make up as much as 50% to 60% of the clayey parts and 15% of the sandy parts of the deposits. It is accompanied by barite, apatite, calcite, dolomite, and opal.

DISTRIBUTION OF DEPOSITS AND CURRENT ACTIVITIES

Fluorspar deposits occur worldwide. The average ore grade of major fluorspar deposits that have been mined has ranged from a low of about 11% CaF_2 (South Africa) to 85% CaF_2 (Mexico). The following discussion addresses the major countries that currently produce fluorspar. The section on the United States is primarily a review of historical production and the geology of the Illinois–Kentucky Fluorspar District. Production is known to occur in other countries, such as Hungary, Iran, Romania, South Korea, and Turkey, but production is limited and information is scarce.

North America

Canada

The only large fluorspar production in Canada was from the St. Lawrence Area of the Burin Peninsula in southern Newfoundland. More than 4.2 Mt of ore was produced by underground mining between 1933 and 1978, when operations ceased. Production resumed in 1987 under new ownership, but ended in 1990 when the mining company went into receivership. In 2004, plans to restart mining as an open-pit operation were under consideration.

On the Burin Peninsula, fluorspar occurs in veins in granite and rhyolite porphyry along steeply dipping faults. The average thickness of higher grade veins is 1 to 2 m and that of lower grade veins is 4 to 6 m. Some veins have been traced on the surface for more than 2 km.

Other deposits occur in British Columbia, Ontario, and Nova Scotia. In British Columbia, the rare deposits at Birch Island, Eaglet, a group of significant occurrences north of the Laird River, and the Rock Candy fluorspar mine. The Rock Candy fluorspar mine, located 25 km north of Grand Forks, operated between 1918

and 1929, and briefly during World War II. The Birch Island deposit, 130 km north of Kamloops, contains reserves estimated at 1.8 Mt grading 29% CaF_2 , and the Eaglet deposit, located near Quesnel Lake, contains 24 Mt of ore grading 11.5% CaF_2 . In Ontario, deposits are located at Madoc and also near Wilberforce and Cobden (Andrews and Collings 1993). Between 1905 and 1961, nearly 122 kt of mostly metallurgical grade were shipped from mines in southern Ontario. The dominant fluorspar-producing area was near Madoc, where five properties—the Rogers, Bailey, Noyes, Kilpatrick, and Perry mines—accounted for 93% of Ontario's recorded fluorspar shipments. At Madoc, fluorspar occurs as small veins that have been worked principally in wartime (Kilborn Ltd. and Mineral Development Section, Ministry of Northern Development and Mines 1991). In Nova Scotia, there is the Lake Ainslie deposit on Cape Breton Island (Zurowski 1972).

Mexico

Mexico has been a major producer of fluorspar since the mid-1950s when major deposits were first developed in the state of San Luis Potosi. Production peaked in the period from 1971 to 1975, when annual production regularly reached 1.0 to 1.2 Mt. Production has varied tremendously in the period since 1975, hitting a high of 1.1 Mt in 1981 and a low of 235 kt in 1994. In 1995, production jumped to above 500 kt, and from 2000 to 2002, it averaged between 600 kt and 635 kt, according to official government statistics. In 2002, production was reported at 622 kt, including 279 kt of metallurgical grade and 343 kt of acid grade (U.S. Bureau of Mines 1955–1994; U.S. Geological Survey 1995–2004). Industry estimates put production even higher. The producing mines and mills, in descending order of production, are Cia. Minera Las Cuevas (in San Luis Potosi), Fluorita de Mexico (in Coahuila), Minera Musquiz (in Coahuila), Minerales y Productos Metallurgicos (in Durango), and Minera Ramos (in Coahuila). There are also a number of small mines that produce metallurgical grade and/or feed material to some of the larger producers.

Many types of deposits are mined. In the Musquiz District of northern Coahuila, mantos in Cretaceous limestones are most important. Northwestern Coahuila has vein deposits and replacement deposits in limestone associated with rhyolite sills and plugs. Deposits in the Paila District of central Coahuila are veins. In San Luis Potosi and adjoining Guanajuato, there are several large replacement deposits in Cretaceous limestone unconformably overlain and intruded by Tertiary volcanic rhyolites. Generally, the ore bodies occur along the contacts between intrusive rhyolites and the limestone. The largest is at Las Cuevas where the fluorite is mostly cryptocrystalline in texture and varies in color from near white through various shades of red and purple to near black. Las Cuevas has one of the largest ore bodies in the world with the highest ore grade (on average 85% CaF_2) of any major producer and is a major producer of both metspar (metallurgical-grade fluorspar) and acid-spar (acid-grade fluorspar). Numerous small-vein deposits occur in Chihuahua. Occurrences of fluorspar gangue in metal sulfide mines have provided significant production from differential flotation of the sulfide mill tailings near Parral.

United States

There are no active fluorspar mines in the United States. Hastie Mining (at Cave-In-Rock, Illinois), Seaforth Mineral & Ore Company (at East Liverpool, Ohio), and Oxbow Carbon and Minerals LLC (at Aurora, Indiana) all wash, screen, and dry fluorspar imported or purchased from the U.S. National Defense Stockpile.

Fluorspar deposits, all now idle, are known in 15 states: Alaska, Arizona, California, Idaho, Illinois, Kentucky, Montana, Nevada, New Mexico, Oregon, Tennessee, Texas, Utah, Washington, and Wyoming. They are numerous and are described in previous editions of *Industrial Minerals and Rocks* or in *Geology and Resources of Fluorine in the United States* (Shaw and Van Alstine 1976).

The bulk of all fluorspar mined in the United States came from the Illinois–Kentucky Fluorspar District, which was the source of the last major fluorspar mining operation in the United States (Ozark–Mahoning Company, closed in late 1995). For a number of years, the Illinois–Kentucky District was the world's largest producer (Baxter, Bradbury, and Hester 1973). Shipments of fluorspar concentrates of all grades during the period 1880 through 1995 are estimated to have totaled 11.5 Mt, which is probably equivalent to mine production of approximately 35 Mt of crude ore. Activity in the district is now confined to Hastie Mining.

The following is a general description of the geology and ore deposits of the district. Although vein deposits are numerous, after 1950, bedded deposits near Cave-In-Rock became the source of most of the district's output and outranked the vein deposits in terms of total district production.

Vein deposits of the Illinois–Kentucky District occur along an extensive and intricate system of faults in sedimentary rocks of Mississippian age. Most of these faults are the steeply dipping normal type, trending northeast, with displacement ranging from a few meters to more than 300 m. The most important deposits are on faults of 15 to 150 m displacement. Veins generally range in width up to 4 m and to as much as 18 m in exceptional cases. They have been mined for as much as 270 m vertically and for as much as 3 km along faults. Veins pinch and swell horizontally and vertically with the proportion of fluorspar to total vein material ranging from 0% to 100% within short distances. Near the surface, and to depths as great as 75 m, the veins contain much clay because of the dissolution of vein calcite and limestone wall rock by circulating groundwater, which leaves behind the argillaceous material originally in the limestone. Strong walls are found at depth in most places. A large inflow of water at high pressure was characteristic of the deeper mines, particularly those at Rosiclar (Baxter, Potter, and Doyle 1963; Baxter and Desborough 1965; Baxter, Desborough, and Shaw 1967).

Major replacement deposits occur in Illinois adjacent to a major structure, the Rock Creek Graben (Baxter, Potter, and Doyle 1963). These include deposits of the Cave-In-Rock District, located on the southeast side of the graben, northwest and north of the village of Cave-In-Rock, and the Harris Creek District, approximately 6 km northwest of the Cave-In-Rock ore trend and on the northwest side of the graben (Baxter and Bradbury 1989). Other replacement deposits are in Kentucky, south of Carrsville, and near Hampton, in Livingston County.

Fluorite, accompanied by sphalerite and galena in many ore bodies, is the principal mineral in replacement deposits. Quartz, barite, and calcite are common, along with pyrite, marcasite, witherite, and strontianite. Banded ore, known locally as coontail ore, is characteristic of some deposits and may be a relic from the replaced limestone or may result from rhythmic metasomatic deposition. Crude ores have 15% to 90% calcium fluoride; some contain up to 3.5% zinc and 5% lead.

Residual deposits have been less important producers but have yielded high-quality fluorspar. These gravel-spar deposits are as much as 20 m wide and extend to depths of 30 m or more. The fluorspar occurs as weathered fragments, which range from boulder-size down to that of sand grains, dispersed in a clayey matrix.

Hicks Dome, an intrusive structure in southern Illinois, has been explored for fluorspar with inconclusive results.

South America

Argentina

Vein deposits have been mined intermittently in the Sierra Comechigones, 50 km northwest of Córdoba, and some have been developed for production in the southern part of Rio Negro Province and the adjoining northern part of Chubut. In recent years, metspar has been produced from a group of veins in the Sierra Grande District of Rio Negro, including the Delta vein, reportedly with 4.0 Mt of drill-indicated ore of 51% CaF_2 grade. A small flotation mill at Valcheta formerly produced concentrates for domestic use. In Chubut, a number of veins were discovered west of Puerto Madryn. The ore was used to supply a small 10-ktpy flotation mill that was operated in Chubut from 1984 through 1990. Production was 9.1 kt in 2001 and 7.7 kt in 2002.

Brazil

Brazilian fluorspar reserves, estimated at 1.7 Mt, are located in the states of Santa Catarina (55%), Paraná (33%), and Rio de Janeiro (12%). Production in 2002 was 48 kt from three operations in Santa Catarina and one in Rio de Janeiro, divided into acid grade (68%) and metallurgical grade (32%) from a run-of-mine output of 132 kt (Peçanha 2003). In 1989, at Cerro Azul, a 55-ktpy flotation mill started operation based on output from an alkaline replacement deposit. It proved to be uneconomic and was closed in 1999. The open-pit workings were backfilled and seeded according to Brazilian environmental standards. Small-scale, intermittent production has been reported from deposits in the provinces of Rio Grande do Norte, Paraíba, and Bahia. Brazilian production was 43.7 kt in 2001 and 47.9 kt in 2002.

Europe

France

Deposits occur in the departments of Haute-Loire, Pyrénées-Orientales, Var, Tarn, Saône-et-Loire, and Puy-de-Dôme. Details have been described in a series of articles by Chermette (1972–1973, 1979).

Epithermal vein deposits occur in the Morvan, Auvérgne, Limousin, and Albi districts of the Massif Central, the Maures and Esterel districts of the Mediterranean coastal area northeast of Toulon, in the eastern Pyrénées west of Perpignan, and in the Vosges. The vein deposits contain about 50% CaF_2 , 20% silica, 5% to 10% barite, and 3% to 5% sulfides.

Stratiform deposits with about 35% CaF_2 and 15% barite occur in the Morvan District. Deposits having stratiform characteristics have been important producers in the Escaro District in the Pyrénées southwest of Perpignan. Deposits at Le Beix, Chailac, Chavaniac, and Le Maine in the Massif Central are exhausted. Fonte Sante, La Charbonnière, and Langeac have also closed. Le Burg and Montroc (near Albi) are the only mines currently active. Fonte Sante was noteworthy for the economic occurrence of sillite (MgF_2), which was blended with fluorspar when fed to an HF plant.

Société Générale de Recherches et d'Exploitation Minière (Sogerem), a subsidiary of Groupe Pechiney (now part of Alcan), is the sole remaining producer and operates mines and a beneficiation plant about 20 to 30 km southeast of Albi in the Tarn region. The ore is in silicified breccia in Cambro-Ordovician sericitic schists and averages about 50% CaF_2 with negligible arsenic, bismuth, and lead. Mill capacity is about 110 ktpy, although the flotation plant was recently upgraded and the capacity may be higher.

Germany

The former East Germany normally produced about 100 ktpy of acid-grade fluorspar, in a market insulated from outside competition. Its two principal flotation mills were located at Ilmenau-Gehren in Thuringia and at Lengenfeld in Saxony, each deriving its feed from nearby mines exploiting vein deposits. Following reunification in 1989 and the freeing of markets, these operations were noncompetitive and production ceased in late 1990 and early 1991.

Production in the former West Germany is limited to one surviving mill, operated by Sachtleben Bergbau GmbH, at Wolfach in the Schwarzwald, using ore from vein deposits in the nearby Clara mine. Acid-grade fluorspar rated capacity is about 50 ktpy, produced in conjunction with barite from two parallel veins. The barite vein averages about 48% barium sulfate (BaSO_4) with 15% CaF_2 ; the fluorspar vein has about 39% CaF_2 and 11% BaSO_4 . Fluorspar production in 2002 was estimated at about 32 kt.

Italy

Italy produced 30 to 35 kt in 2003, down markedly from about 80 kt in 1990. Mines in the Gerrei District of Sardinia are the only significant producers, producing ore from one of the world's longest and most persistent vein systems on which four underground mines have been linked along the strike into a single producing unit. The Genna Tres Montis-Muscadroxio-S'Acqua Frida vein system in southern Sardinia, near the village of Silius, is credited with 8 Mt of ore reserve averaging 40% to 45% CaF_2 , making it one of the world's largest deposits. Vein widths are 5 to 8 m. Barite and galena are recoverable accessory minerals. Underground workings have demonstrated a strike length of about 3 km. Numerous other vein deposits and a skarn deposit occur in southern Sardinia.

Nuovo Mineraria Silius SpA is now the only producer, operating a flotation plant at Assemini, near Cagliari. The plant has a capacity of about 100 ktpy of acid-grade concentrate and metspar briquettes, in addition to barite and galena concentrates. An older mill with acid-grade capacity of 40 ktpy is idle.

In northern Italy, important deposits have included Prestavel and Vallarsa near Bolzano, Torgola near Brescia, and Camerata Cornello near Bergamo, all of which are now closed.

The Pianciano deposits in the Castel Giuliano Area, 40 km northwest of Rome, consist of fluorspar that impregnates lake beds of volcanic ash (Spada 1969). The fluorspar content, ranging from 20% to 55%, was derived from volcanic emanations along with barium, strontium, and phosphorous. The fluorspar is too fine-grained to be recovered economically.

Spain

Spain is estimated to have produced about 140 kt of metgrade and acid-grade fluorspar in 1990—20 kt metallurgical grade and 120 kt acid grade, all from the Asturias region. Output remained essentially level at 130 kt in 2002.

Principal deposits are in the Asturias region of northern Spain, near the ports of Ribadella and Aviles; in southeast Spain, near the port of Almeria; and in south-central Spain, near Seville and Cordoba. Deposits are both vein and replacement bodies. Acid-grade material was formerly derived by the retreatment of old lead mine wastes in the Almeria-Berja Area. In 1980, seven companies produced acid-grade fluorspar—four in Asturias, two in the Seville-Cordoba region, and one near Berja. Grades of ore range from 40% to 45% for some of the vein mines, down to 15% to 20% in the case of the old lead mine waste. The large Oso vein in Gerona is exhausted. Weakening market conditions and competition from China have led to closure of all except one mill, located at Ribadesella and belonging to Minerales y Productos Derivados (Minersa).

United Kingdom

Among numerous fluorite occurrences in the United Kingdom, the most recent operations are located in the Southern Pennine Ore-field of north Derbyshire and in the Northern Pennine Ore-field of west Durham. Production is from fissure veins and bedded replacement deposits, together with associated old lead mine waste and tailings dumps. The deposits occur in rocks of the Carboniferous Limestone Series (Mississippian). Ore is currently mined both underground and by open pit. The deposits contain variable amounts of galena, sphalerite, calcite, barite, quartz, and iron sulfides. Some were originally mined for lead, even before written record.

Fluorspar and barite-bearing ores have been processed in Derbyshire since 1938, initially by Glebe Mines and then by Laporte Minerals. LRM Ltd. acquired the business assets of the Laporte operation in November 1999. The operation continues as a wholly owned subsidiary of LRM, renamed Glebe Mines. The underground mining operations are on Glebe Mines' property and external contributors provide ore from nearby privately owned open-pit operations for processing at Glebe's Cavendish Mill. Glebe Mines is the only remaining producer of fluorspar in the United Kingdom and supplies acid grade to both of the hydrofluoric acid producers; production in 2002 was about 45 to 50 kt and rose in 2004 to its previous output of 60 ktpy. The operation at Broadwood on the Northern Pennine Ore-field ceased producing fluorspar in 1999 and now functions as a limestone quarry.

Africa

Kenya

All production is from a single acid-grade plant, formerly jointly owned by the Kenyan government, International Minerals and Chemical Corporation, and the Bamburi Portland Cement Company, then solely by the Kenyan government from 1979 to January 1997, when it was fully privatized under entirely new management. Acid-grade production was 103 kt in 2002. In 2003, it was approximately the same, and will expand to about 135 kt in 2006. It produces concentrates relatively high in phosphorous pentoxide (P_2O_5 ; about 0.43%) from epithermal vein and replacement deposits in the Kerio Valley, about 130 km northwest of Nairobi. Ore ranging from 30% to 45% CaF_2 is open-pit mined. Concentrates are trucked 45 km to rail at Kaptagat, near Eldoret, and then 884 km to port at Mombasa.

Morocco

The El Hammam deposit near Meknes consists of two nearly vertical veins, mineralized in a fish-bone pattern at intervals along an east-west fault in sericite schist and shales. Overall length is more than 2.5 km with ore widths of 2.5 to 5 m, grading about 45% CaF_2 . The mine and the flotation plant, with a capacity of 110 ktpy of acid-grade concentrate, are operated by Societe Anonyme d'Entreprises Minières (Samine) and are owned by Omnium Nord Africain (58%) and by the Moroccan government through the Bureau de Recherches et de Participations Minières (42%). Three other deposits are recognized in this region. Other veins occur in the Djebel Tirremi area, 10 km northeast of Taourirt, in eastern Morocco (Van Alstine and Schruben 1980).

Namibia

The principal fluorspar deposits are on the Marburg farm, with lesser deposits on the adjacent Okorusu, Belvedere, and Brandenburg farms, located about 20 km northwest of Ojijwarango, which is 425 km northeast of the port of Walvis Bay. These fluorspar deposits are part of an alkalic complex that forms an erosionally broken ring

structure about 5 km in diameter. The fluorspar bodies lie mainly in the southern part of the complex where they occur, with accompanying thin magnetite cappings, as late metasomatic replacements of syenite, fenitic rocks, and carbonatite (Schneider and Seeger 1990). Reserves exceed 6 Mt, grading about 60% CaF_2 and about 5% P_2O_5 . A flotation mill, rated at 50 ktp y, began operation in 1988 under Okorusu Holdings Ltd. The mine and mill were sold to Solvay Group of Brussels, Belgium, in 1997. It is managed through Solvay Fluor und Derivate in Hannover, Germany, which instituted significant expansion of the mine and mill to provide an output of about 100 ktp y, all of which is consumed by Solvay for production of HF at Bad Wimpfen in Germany and at Porto Maghera in Italy (*African Mining* 2003).

South Africa

Fluorspar, mainly acid grade, is produced at two mine/mill operations: Vergenoeg Mining near Pienaar srivier, 80 km nor theast of Pretoria, and the Witkop fluorspar mine near Zeerust, about 250 km west of Johannesburg.

Vergenoeg Mining, which is 70% owned by South Africa's Metorex Group and 30% by Spanish fluorspar producer Minersa, has an open-pit mine in a nearly 2-billion-year-old volcanic pipe that constitutes the fluorite ore body. The ore body is hosted by the Rooiberg Group rhyolites, centrally located between the four lobes of the Bushveld Complex. The ore body has a vertical funnel-like shape about 900 m in diameter at the surface, tapering sharply at depth to where it is still open-ended below 650 m. The pipe is horizontally zoned, with a hematite-fluorite or gossan cap at the surface, below which is a deeper zone of magnetite-fluorite, then a magnetite-fayalite transition zone, and finally a fayalite zone at the deepest levels. Hematite-fluorite, magnetite-fluorite, and magnetite-fayalite assemblages make up more than 90% of the mineralogical composition. Fluorite occurs in both massive and disseminated form and is present in variable quantities throughout the pipe. The fluorite-rich part of the ore body extends to a depth of approximately 360 m. The ore grade is between 35% and 40% CaF_2 , and present mining depth is 55 m. The mine produces about 120 ktp y of acid grade and 10 to 20 ktp y of metallurgical grade (Metorex Limited, undated).

In the Zeerust District, fluorspar occurs as replacements in dolomite and in associated residual deposits. Much of the ore is disseminated in dolomite along intersecting fractures. For many years, metspar was produced by screening coarse fragments from residual surface deposits. The current operation is the Witkop fluorspar mine, a subsidiary of South African Land & Exploration Company (Sallies). The previous mine owners were selectively mining the high-grade ore, but after a thorough investigation of the ore body, new management has found it possible to maintain a target ore grade of 11%, which will prolong the life of the mine. Current reserves from the Wintershoek deposit (currently being mined) plus the company's Buffleshoek reserve total 27.5 Mt, reportedly at a final grade of 14.5% CaF_2 . The company recently purchased new mining equipment and performed extensive drilling to establish best mining practice. Additional milling and flotation capacity was added and intensive metallurgical research performed to determine the best combination of flotation collectors and depressants to improve flotation recovery. Capacity increased to 180 ktp y with improvements completed in 2004 (Lanham 2004).

The former Buffalo open-pit mine of Transvaal Mining and Finance, a subsidiary of General Mining and Finance near Naboomspruit, exploited 14% to 16% grade deposits consisting of a network of fluorspar veinlets in sill-like bodies of fine-grained, pink granite in coarse, red Bushveld granite. In 2000, International Metals Process-

ing acquired the mine and attempted to produce acid-grade product by processing feed from preexisting high-grade stockpiles and tailings dumps. Operations ceased in 2002, apparently as a result of legal problems.

Acid-grade fluorspar is exported to Australia, Europe, Japan, and North America through the port at Durban. Domestically, acid grade is consumed by African Exploratives and Chemical Industries Ltd. to make hydrofluoric acid, and the steel industry consumes essentially all of the metallurgical-grade fluorspar.

Tunisia

A former flotation mill, located at the Hammam Zriba deposit near Zaghouan, 54 km south of Tunis, produced about 30 ktp y of acid-grade concentrate from a bedded deposit in Jurassic limestone, averaging 35% CaF_2 with considerable barite. In the same general area, replacement vein deposits occur at Djebel Staa, Hammam Djedida, Djebel Oust, and Djebel el Kohol. Other deposits are at Bourchiba, Cap Bon, and Bou Ja ber. Production in Tunisia ceased in 1992, and the country now imports about 75 ktp y of acid-grade fluorspar to supply the aluminum fluoride plant of Industrie Chimique de Fluor (ICF) in Gabes.

Asia

China

This country is the world's largest fluorspar producer with a production of about 2.45 Mt in 2002, of which about 1.25 Mt was acid grade and 1.2 Mt metallurgical or submetallurgical grade. Principal deposits are in the central and northern parts of Zhejiang, in eastern Fujian, northeastern Hebei, eastern and southern Hunan, northern Guangdong, northeastern Anhui, eastern Shandong, Inner Mongolia, and Liaoning. In all, fluorspar occurrences are reported in 17 provinces.

In 2002, according to the United Nations Statistics Division, Commodity Trade Statistics Database (Comtrade), exports of acid-grade fluorspar were about 807 kt (902 kt in 2001) and exports of metallurgical grade were 200 kt (208 kt in 2001). Of the acid-grade exports, 359 kt went to the United States (344 kt according to U.S. import statistics) and 202 kt went to Japan. These figures compare to exports of 170 kt of acid grade to Japan and about 125 kt to the United States in 1990.

Acid-grade production has mushroomed with production from as many as 40 flotation mills (down from more than 80 in the mid-1990s). Some originated from conversion of preexisting mills and others from new construction. Most of the fluorspar deposits now being mined in China are veins in acidic terranes. One in De An in Jiangxi Province is a series of large replacement ore bodies.

India

At Amba Dongar, 560 km north of Bombay in Gujarat State, veins and replacement bodies occur in the carbonate wall rock around ankeritic carbonatite intrusives, similar to the occurrences at Okorusu in Namibia (Deans et al. 1972). A heavy media and flotation concentration plant has been constructed nearby at Kadipani, with a nominal capacity of 37.5 ktp y of product, of which 30% is acid grade with a high P_2O_5 content and 70% is metallurgical grade. Reserves are reported to be 11.6 Mt of 30% fluorite content, of which proven reserves are said to be 4.7 Mt (Moorthy 1997).

Other mineralized areas are reported at Chandri-Dungri in the Drug District of Madhya-Pradesh and at Mando-ki-Pal in the Durgapur District of Rajasthan.

Mongolia

The major fluorspar production site in Mongolia is the mill at Bor Undur, which is fed by four mines at Bor Undur, Khajuu Ulaan,

Ayrag, and Urgun. Fluorspar deposits occur in breccia and veins composed of fluorite, calcite, and quartz associated with Late Permian faults. Fluorspar production at Bor Undur started in 1982 as a joint venture (Mongolrostsvetmet) of the Mongolian Peoples Republic and the former USSR. Mining was followed by the construction of the flotation mill in 1985. Improvements were made to the mill beginning in 1998 that increased its capacity from 130 ktpy to 160 ktpy. Production in 2002 was reported to be about 130 kt of acid grade (95.5% to 97.2% CaF_2) and 80 kt of metgrade (75% CaF_2).

In 2003, a new joint venture was formed (Mongolia Minerals Corporation) to mine, process, and export fluorspar. They are apparently reselling acid grade purchased from Mongolrostsvetmet and producing metallurgical grade from a mill in the Ayrag region. The company is studying plans to build a flotation plant to produce acid grade and an aluminum fluoride plant to add value to its exports (Crossley 2004).

Russia

There are reportedly four major active companies in the Russian fluorspar industry: JSC Yaroslavsky, JSC Zabaikalsky, JSC Kalanguisky, and Suran Cooperative Quartz, with production concentrated in southeast Russia and Siberia. By far, the largest producer is Yaroslavsky GOK (also known as Yaroslavsky Mining and Dressing Complex), which mines the Vosnesensky and Pogranichny deposits in the Primorsky region of the Russian Far East. Russia produced 169 kt of fluorspar concentrate in 2002, of which Yaroslavsky accounted for 70% to 80%. The South-Ural and Polevskoy cryolite plants consume more than 90% of Yaroslavsky's output, but domestic production satisfies only half of Russia's needs. The balance is imported from Mongolia (Crossley 2004).

Thailand

Fluorspar deposits occur in a region extending from the northern border with Burma southward for more than 1,280 km to a point about 640 km southwest of Bangkok. Mining was concentrated in three areas: Chiangmai, Lamphun, and Mai Hong Sun provinces in the north; Kan Chanaburi, Petchaburi, and Ratchaburi provinces southwest of Bangkok; and Krabi Province in the south (Gardner and Smith 1965; Hodge, personal communication), but production has fallen to less than 5 ktpy, all from Mai Hong Sun.

Vietnam

Tiberon Minerals Ltd., a Canadian corporation, is studying development of acid-grade fluorspar production in connection with a new polymetallic mine and mill planned for start-up in 2007 in northern Vietnam at Nui Phao. The Nui Phao deposit is primarily a polymetallic intrusive skarn (tactite) and greisen ore body. The mineralization is characterized by an assemblage of tungsten-gold-copper-bismuth-fluorine-bearing minerals that occur within and proximal to a biotite-muscovite granite. Project interest is held 77.5% by Tiberon, 15% by Thai Nguyen Mineral Company, and 7.5% by Export-Import Investment Company Thai Nguyen. An exploration license on 91 km^2 is held by Tiberon. Drilling of 180 holes has indicated a resource of 88 Mt grading 0.22% WO_3 (tungsten trioxide), 8.0% CaF_2 , 0.22% Cu (copper), 0.24 g/t Au (gold), and 0.11% Bi (bismuth). Preliminary plans are to produce about 200 ktpy of low-arsenic, acid-grade fluorspar from ore mined at the rate of 3.5 Mtpy. An existing railroad crosses the property and links it to the port at Hai Phong, 160 km away (Tiberon Minerals Ltd. 2004).

Australia

Deposits of fluorspar have been found in all the Australian states except the Northern Territory (Liddy 1971) but are undeveloped

because they are small and remote. There have been investigations in the Chillagoe-Mungana-Almaden and Forsyth areas of northern Queensland, and in western Australia in the Pilbara District, 217 km southeast of Port Hedland; the Yinnietharra Area, 320 km from Carnarvon; and the Speewah Valley area 180 km southwest of Wyndham.

As reported at the 2003 Fluorspar Conference in Rome, recent activity at Speewah involves feasibility work started in August 2003, anticipating an 18-month construction program aimed at 180 ktpy production of low-arsenic acid grade.

EXPLORATION AND MINING METHODS

Because fluorspar resists chemical weathering, it can be traced in the soils of heavily weathered veins. Cleavage fragments, washed clean by rainwater or exposed in anthills or spoil piles from animal burrows, are useful clues. Silicified veins, resisting erosion, may stand up like a reef. Bedded deposits are less discernable, but, in areas of sufficient topographic relief, the outcropping edges of deposits or slumped fragments of ore may be found. Because of its softness and cleavability, fluorspar does not survive in the beds of streams and ordinarily cannot be traced by panning.

The search for bedded deposits usually involves locating a mineralized horizon and following it down dip with vertical drill holes, drilled to intersect the favorable beds. Geophysical prospecting methods are not applicable. Photogeology can be of assistance in locating and tracing structures and outcrops, and as an aid in geologic mapping to determine the areal distribution of stratigraphic units known to be favorable for veins or replacement deposits.

Geochemical methods have been employed with varying degrees of success. Fluorine anomalies have been found in groundwater and surface streams, in soil samples, and in stream sediments, but using such anomalies as a prospecting tool for the discovery of ore deposits has not been very successful. Various nonfluorine elements that can be detected geochemically can be guides to fluorspar deposits, and in soluble residues of potential host-rock limestones can serve as a sample medium (Erickson et al. 1987). Once mineralization has been detected, core or churn drill holes, prospect shafts, and drifts may be used to probe the structures.

Mining Methods

In some areas, veins may be weathered to depths of as much as 75 m. Such weathered ore, a mixture of clay and fragments of fluorspar and detached wall rock, may be mined open pit with draglines, scrapers, or power shovels to depths of as much as 50 m. Below that, underground mining methods, involving modified top slicing or overhead shrinkage stoping, are used.

Vein mining is commonly done by shrinkage stoping, cut-and-fill, and open stoping where strong walls occur. Closely spaced shrinkage stope bins may give way to widely spaced bins, with electric and air slushers being used in the tops of stopes to transport the overbreak to the ore pass. Air-operated, rubber-tired, muckhaul units can be adapted to in-stope work. Where shrinkage stoping is used, broken ore is commonly moved to the shaft by track haulage using battery-powered locomotives and 1- or 2-t side-dump cars.

With the introduction of diesel haul units of less than 1.5 m in width, mining can be changed from shrinkage stoping to ramp subleveling in veins. Loaders can be served by small diesel trucks carrying 3 to 4 t. Ventilation for the diesel equipment is usually handled by lines of woven plastic tubing. In shafts, bucket hoisting is supplanted by lifting in larger skips. In larger mines, crushers are installed over skip-loading pockets at the shaft bottom, which improves skip loading.

In bedded deposits, room-and-pillar patterns are used, with the widths of rooms governed by roof conditions. Newer equipment has rubber tires and is diesel operated, including the muck haul units—which have buckets ranging in size from 0.9- to 4.6-m³ capacity—and rubber-tired diesel trucks with 3- to 18-t capacity. Drilling is done by diesel-propelled jumbos in the bedded ore mines, but the jackleg drills are still used in narrower working places and drifts. In multileveled ore bodies, haulage ramps on 12% to 15% grades connect the levels. Vertical raises are used to facilitate ventilation requirements. Most drilling uses tungsten carbide bits, or the throw-away-type hardened steel bits. In blasting, the trend is increasingly toward the use of ammonium nitrate-fuel oil mixtures. Mine crews, supervisors, and mechanics are usually provided with diesel personnel vehicles to facilitate mobility.

Wherever widths of ore bodies, depths of overburden, economic stripping ratios, and the strength of the sidewalls permit, it is common practice to mine by open-pit methods, as is the case in Kenya and South Africa. This optimizes the obvious advantages to be gained by using lower cost explosives, large-scale earth-moving equipment, and economical quarry bench mining methods.

Methods of Beneficiation

Most fluorspar must be upgraded for marketing. The beneficiation techniques used are tailored to meet the character of the ores and the specifications for particular uses.

In countries with abundant low-cost labor, metallurgical spar with a calcium fluoride content in the range of 75% to 85% is often produced by the hand sorting of high-grade lump crude ore, followed by crushing and screening to remove most of the +10-mesh fraction. In the case of ores of lower grade, and/or ores with relatively coarse interlocking of minerals, gravity processes of concentration are used for producing metspar based on the specific gravity of spar and less than 2.80 for most gangue minerals.

Heavy media cone and drum separators are particularly effective in the size range of 0.5 to 3.8 cm, either for producing metallurgical gravel or for preconcentrating the crude ore for flotation feed. For the finer sizes, the heavy media cyclone process is frequently used. The high tonnage capacity and low operating costs of heavy media methods give very satisfactory results. The sink can be soild as metspar and the sands for flotation feed, and the float is frequently marketed for road gravel and concrete aggregate. Ores as low as 14% CaF₂ are being preconcentrated to yield a flotation feed of 40% CaF₂ or more. Lead and zinc sulfides and barite, because of their high specific gravity, concentrate with the fluorspar to enrich the flotation feed in these valuable minerals. Many ores that would otherwise be too low grade to warrant mining and processing can be preconcentrated to acceptable flotation feed grade with a tailings loss of less than 12% of the CaF₂ in the crude ore. Washing plants are also used ahead of flotation to remove clay or wad (manganese oxides) in some areas. Barite, a fairly common accessory mineral in fluorspar deposits, can be effectively separated from the fluorspar by flotation and, in most instances, made into a salable product.

Acid-grade concentrates are produced by the froth flotation process, which takes advantage of the varying surface properties of different minerals allowing separation in flotation cells. The run-of-mine ore is crushed and ground to a size that liberates the individual minerals, enabling their separation. Care is taken in grinding to avoid producing extremely fine sizes, known as slimies, which are not amenable to subsequent separation in the flotation process.

The flotation feed first goes to conditioners for reagent addition. The resulting pulp is agitated in the presence of injected air, which creates minute air bubbles that attach to the desired mineral by means of a collector reagent that is then floated off in a froth. If

sulfides are present, they are floated first by use of a xanthate collector in a circuit ahead of the fluorspar; first lead sulfide, then zinc sulfide. Next, easily floated fluorspar is collected in a rougher flotation circuit and is routed directly to the cleaner circuits. Less-easily-floated fluorspar is recovered in a scavenger circuit, and the scavenger tailing is discarded. Where necessary, middlings from up to six stages of cleaning are reground to liberate interlocking grains of fluorspar and gangue minerals. The reground product is then recycled to maximize the recovery of the desired acid-grade concentrate. Commonly used reagents include fatty acids to collect the fluorspar; quebracho or tannin to depress calcite and dolomite; sodium silicate, starch, or dextrin to depress iron oxides and silicates; and dichromates (where environmental regulations allow) to reject barite. Cyanide may be used to depress sulfides. Soda ash and occasionally caustic soda can be used for pH control. In the past, the temperature of the slurry was raised from ambient to as high as 80°C to optimize flotation performance, but the rising cost of energy in recent years has almost eliminated this procedure. Most fluorspar ores can be successfully treated at ambient temperature, even if the source of the water is from below ice, provided that a modern flotation collector containing emulsifying additives is in use.

From the final cleaner circuit, the resulting fluorspar-concentrate slurry with a pulp density of about 25% solids goes to a thickener tank where the density is raised to about 55% solids and the overflow water is recycled to the milling circuit. More water is removed when the thickened slurry passes through vacuum filters where a fluorspar filter cake, usually with less than 10% moisture, is obtained ready for shipment. In some operations, the filter cake is dried prior to shipment in bulk tankers or bags.

The International Organization for Standardization (ISO) has approved 24 standards for testing fluorspar. Some of the more important ones include the following:

- ISO 5439 Acid-grade fluorspar: Determination of a available fluorine content—potentiometric method after distillation (ISO 9503 for metallurgical grade)
- ISO 6676 Acid-grade and ceramic-grade fluorspar: Determination of total phosphorus content—reduced-molybdophosphate spectrometric method (ISO 9438 for metallurgical grade)
- ISO 9505 All grades of fluorspar: Determination of arsenic content—silver diethyldithiocarbamate spectrometric method

Other ISO standards include tests for antimony, barium sulfate, calcium carbonate, iron, lead, manganese, moisture, silica, sulfides, and sulfur. There are additional ISO standards testing other chemical and physical characteristics (ISO 2004).

Internationally traded fluorspar is usually analyzed according to the American Society for Testing and Materials (ASTM) E1506-97 (2003) standard, *Standard Test Methods for Analysis of Acid-Grade Calcium Fluoride (Fluorspar)*. This analytical standard covers the precise procedures to assay the fluorspar filtercake for silica (SiO₂), calcium fluoride (CaF₂), soluble chloride as NaCl, calcium carbonate (CaCO₃), phosphorus (P) as P₂O₅, arsenic (As), mixed oxides (R₂O₃), sulfide sulfur (S), and volatiles as moisture (H₂O).

LOCATION OF BENEFICIATION FACILITIES WORLDWIDE

It is difficult to maintain a comprehensive and up-to-date list of fluorspar flotation mills. Some are major and prominent producers that are well known in the export market; many others are small and little known outside their country of operation. In China, for example, there are so many that it is impractical to list them all, but Wei (1999) and Will and Ishikawa (2002) provided comprehensive lists in their reports.

Some of the major active flotation mills are located as follows:

Location	Company	Capacity, ktpy
Africa		
Kenya	Kenya Fluorspar Company	103
Morocco	Samine	110
Namibia	Okorusu	100
South Africa	Vergenoeg	120
	Witkop	100
Asia		
China	Various	Various
India	Gujarat	20
Mongolia	Mongolrostsvetmet	160
Russia	Yaroslavsky	200
Europe		
France	Sogerem	110
Germany	Wolfach	50
Italy	Nuovo Mineraria Silius	100
Spain	Minersa	130
United Kingdom	Glebe Mines	60
North America		
Mexico	Las Cuevas	500
	Fluorita de Mexico	115
	Minerales y Productos Metallurgicos	20
	Minera Ramos	15

MARKETING

Product Specifications

Traditionally there have been three principal market grades of fluorspar—acid, ceramic, and metallurgical. Specifications for acid grade and metallurgical grade are fairly well defined although the requirements set by individual consumers may vary in detail.

Acid-grade fluorspar is defined as containing more than 97% CaF_2 , but some manufacturers of hydrofluoric acid, both in the United States and in Europe, can use 96%, or slightly lower, if the remaining impurities are acceptable. The Russian specification for acid spar from the Mongolian flotation mill at Bor Undur is not less than 92% CaF_2 . Users specify limits for silica, calcium carbonate, arsenic, lead, sulphide sulfur, phosphorus, and other deleterious constituents. Moisture content of dried concentrates for acid and ceramic grades is usually specified to be not more than 0.10% H_2O , but in some ceramic uses, up to 1% or 2% may be required to relieve dust problems in handling bulk materials.

In the United States, the use of ceramic-grade fluorspar has declined, but it is still offered by some suppliers. There are basically two grades—ceramic no. 1 (90% to 95% CaF_2) and ceramic no. 2 (85% to 90% CaF_2)—although some former consumers of ceramic grade now use an acid grade. Some foreign fluorspar suppliers still offer ceramic grade, but because practically every ceramic-grade user has its own specifications, suppliers (foreign or domestic) may tailor their products accordingly or offer several product grades that fall between metallurgical grade and acid grade. Customers may specify limits on silica, calcite, ferric oxide, and lead and zinc sulfides.

In the United States, metallurgical-grade fluorspar generally contains a minimum of 80% CaF_2 and can range as high as

93% CaF_2 . Impurities of concern for steel customers are silica (4% to 10% maximum) and calcium carbonate (4% to 9% maximum). Standard size specifications for metallurgical-grade fluorspar gravel are 100% passing a 63-mm (2.5-in.) screen and a maximum of 15% passing a 9.5-mm (3/8-in.) screen. In markets outside the United States, CaF_2 content may be lower (depending on the country) and acceptable silica content may be higher than the U.S. specification.

Primarily in the steel industry, there was once significant usage of fluorspar as briquettes (containing varying amounts of fluorspar), but with the steel industry's decrease in consumption in the United States, this practice is no longer widespread. There may still be some fluorspar combined with other fluxing materials, such as lime into briquettes; the quantities are, however, thought to be small.

Uses of Fluorspar

Fluorspar is used to make HF (also called hydrogen fluoride or hydrofluoric acid), which is an intermediate for fluorocarbons, aluminum fluoride, and synthetic cryolite. Fluorspar is also used as a flux in the steel and ceramic industries and in iron foundry and ferroalloy practice, and it has many minor specialized uses. Hydrogen fluoride is produced by reacting acid-grade fluorspar with sulfuric acid in a heated kiln or retort to produce HF gas and calcium sulfate. After purification by scrubbing, condensing, and distillation, the HF is marketed as anhydrous HF, a colorless fuming liquid, or it may be absorbed in water to form the aqueous acid, usually 70% HF. Synthetic cryolite, organic and inorganic fluoride chemicals, and elemental fluorine are made from hydrofluoric acid. The acid itself is important in catalysis in the manufacture of alkylate, an ingredient in high-octane fuel for piston-driven aircraft and automobiles; in steel pickling, enamel stripping, and glass etching and polishing; and in various electroplating operations (Roskill Information Services 1993). The manufacture of 1 t of virgin aluminum requires about 12 to 29 kg of fluorine content in synthetic cryolite and aluminum fluoride. Through improved technology (prebaked) and recovery practices, this quantity is being lowered significantly in countries with the most advanced technology (e.g., in the Middle East); others using older technology remain at the high end (e.g., Russia; Cox 1989).

Elemental fluorine is prepared by electrolysis from potassium fluoride and anhydrous HF. Gaseous at room temperature and pressure, fluorine is compressed to a liquid for shipment in cylinders or in tank trucks. Elemental fluorine is used to make uranium hexafluoride, sulfur hexafluoride, and halogen fluorides. Gaseous uranium hexafluoride is used in separating U^{235} from U^{238} by the diffusion process. Sulfur hexafluoride is a stable high-dielectric gas used in coaxial cables, transformers, radar wave guides, and magnesium casting. Halogen fluorides have important applications, mostly as substitutes for elemental fluorine, which is more difficult to handle.

Emulsified perfluorochemicals—organic compounds in which all hydrogen atoms have been replaced by fluorine—are undergoing investigation as synthetic blood substitutes and therapeutic oxygen carriers. They transport oxygen and may be useful in treating surgery and trauma patients. Such blood substitutes would carry no risk of disease transmission, would have a shelf life of up to 2 years, and could be used in patients regardless of their blood type (Robinson 2003).

Inorganic fluorides are used as insecticides, preservatives, antiseptics, ceramic additives, and fluxes, and in electroplating solutions, antioxidants, and many other products. Boron trifluoride is an important catalyst.

Organic fluorides are volume leaders in the fluorine chemical industry. Fluorinated chlorocarbons and fluorocarbons are prepared

by the interaction of anhydrous HF with chloroform, perchlorethylene, and carbon tetrachloride, and are characterized by low toxicity and notable chemical stability. They perform outstandingly as refrigerants, aerosol propellants, solvents, and cleaning agents, and as intermediates for polymers such as fluorocarbon resins and elastomers. Fluorocarbon resins, which are inert compounds that have unusually low coefficients of friction, have found a number of applications as lubricants for parts that cannot be oiled; for example, in bearings for window-raising equipment located inside automobile doors, in small electronic equipment, for the manufacture of chemical resistant gaskets and valve parts, as pipe and tank linings, in flexible tubing and containers, and on nonstick cookware.

In the steel industry, fluorspar is used as a flux in basic open hearth (older technology, no longer widely used), basic oxygen, and electric arc furnaces where it is added to the heats in amounts ranging from 1 to 10 kg/t of steel produced. The average in the United States is at the low end of this range, and many steel plants have discontinued its use entirely. Fluorspar promotes fluidity of the slag (by reducing its melting point) and thus facilitates removal of sulfur and phosphorus from the steel into the slag. It serves the same purpose in iron foundries, where it is added to the cupola charge in the proportion of around 7 to 9 kg/t of metal melted.

In the ceramic industries, fluorspar is used to make flint glass, white or colored opal glasses, and enamels. Flint glass mixtures commonly contain 3% fluorspar. Opal glasses, containing 10% to 20% fluorspar, are used in containers for foods, drugs, and toiletries, and in ornamental glassware and laboratory and restaurant fixtures. Opaque enamels are used to cover steel stoves, refrigerators, cabinets, bathtubs, and cookware, and for facings on brick, tile, and other structural materials. Fluorspar makes up 3%–10% of the weight of the enamel. Many types of welding rod coatings incorporate fluorspar or fluorspar mixtures. Ceramic-grade fluorspar has been used in the manufacture of magnesium and calcium metals, and in the preparation of some manganese chemicals. In current industrial practice, users typically buy acid grade rather than ceramic grade and dilute it proportionately.

Ceramic- and metallurgical-grade fluorspar may be used in making fiberglass insulation, in zinc smelting, as an inhibitor of vanadium green scumming in the manufacture of buff-faced brick, and as an abrasive on certain types of sandpapers. Various grades of fluorspar are used in electric furnace manufacture of calcium carbide, in making electrodes for arc lamps, and as a bonding material for abrasive wheels, among numerous minor uses.

Metallurgical- or submetallurgical-grade fluorspar is used as a flux in cement production. It is added to the mix of cement raw materials before introduction to the rotary kiln. The addition of fluorspar saves fuel by allowing the kiln to operate at a lower temperature. It also helps produce a softer clinker product that is easier to grind, thus saving electrical energy.

Product Pricing

Published fluorspar prices, as reported monthly in *Industrial Minerals* magazine, conform to the two harmonized tariff codes for fluorspar (2529.21.0000 for metallurgical grade and 2529.22.0000 for acid grade). Prices differ by country of supply and are listed on a free-on-board (f.o.b.) basis at the country of origin or on a delivered basis to the first port of entry, which includes the c.i.f.

Historically, normal competition determined product pricing in world markets, but this pattern has been distorted by specific countries that dominated international fluorspar markets at different times. This was evident in the early 1990s, when China drove prices down to levels not seen for years. In 1994, China instigated a program of export quotas and export license fees, which added US\$9,

US\$16, and US\$20 per ton in successive rounds of bidding. These export license fees increased through the 1990s and by 2003 were more than US\$50 per ton.

China's economy has been growing at such a remarkable rate that its domestic fluorspar requirements have grown much faster than anyone could have foreseen. As a result, China has reduced its annual export quota from 1.2 Mt in 2000 to an expected 750 kt in 2004. Initially, the decrease in exports did not have a major impact on world prices, but by 2003 the supply shortage resulted in a major runup in acid-grade fluorspar prices.

Transportation

The United States is dependent on imports for the majority of its fluorspar supply. Most acid-grade fluorspar is transported in bulk to customers by rail, barge, and ship. Acid grade is shipped routinely in the form of filtercake containing 8% to 10% moisture to facilitate handling and to reduce dust. This moisture is removed by drying in rotary kilns, or other kinds of dryers, before treating with sulfuric acid to make HF. Metallurgical grade is shipped routinely as lump or gravel in barges, ships, or railroad cars. Some acid grade and ceramic grade is marketed in bags for small users and shipped by truck.

Fluorspar is shipped by ocean freight using the "tramp" market and time charters. Bulk carriers of 10,000 to 50,000 t deadweight normally are used. Participants negotiate freight levels, terms, and conditions within the limits defined by International Maritime Organization regulations.

Depletion Allowance and Duties

In the United States, the depletion allowance is 22% for domestically mined fluorspar and 14% for foreign operations of U.S. companies. There are no duties on fluorspar imported into the United States; tariffs on metspar (97% CaF_2 or less) and acidspar (more than 97% CaF_2) were eliminated in the late 1990s.

ENVIRONMENTAL FACTORS

In September 1987, the United States and 22 other nations signed the Montreal Protocol on Substances That Deplete the Ozone Layer. The Montreal Protocol and subsequent amendments mandated a freeze on production of chlorofluorocarbons (CFCs), hydrochlorofluorocarbons (HCFCs), and halons, and the eventual phaseout of these compounds. All three are fluorine-containing compounds. Under the umbrella of the Montreal Protocol, specific phaseout schedules have been set for different classes of compounds with different deadlines depending on the country or region. These schedules have been revised periodically as new scientific data have become available. In the early 1990s, the allocated amount of CFCs allowed for production and consumption by developed countries was reduced to 25% of the amount produced in 1986. Production of CFCs had been a major downstream market for fluorspar, and this reduction had a major impact on fluorspar production and demand. World production prior to the phaseout was about 5.46 Mt in 1989 but had decreased to 3.75 Mt by 1994. The market has recovered to some extent, but it is still about 1 Mt below its peak in 1989. This recovery resulted from the development of replacement hydrofluorocarbon (HFC) compounds designed to perform the same or similar functions as the banned CFCs. These consist of compounds such as HFC 134a, which is widely used in refrigeration and air-conditioning systems. HFC 134a actually requires more fluorspar to manufacture than the main compound it replaces (CFC 12).

The fluorspar, HF, and fluorocarbon producers face an uncertain future. HFCs have a relatively high global warming potential, and there is a push to have them phased out as part of the Kyoto

Protocol to the United Nations Framework Convention on Climate Change. This is already having an impact in the European Union, which is a strong supporter of the Kyoto Protocol.

OUTLOOK

Fluorocarbon production from HF is the single largest market that drives acid-grade fluorspar demand. In 2003, the ban on production and importation of the widely used blowing agent HCFC 141b went into effect. The expected loss of market share to nonfluorocarbon replacements will be significant. Some sources estimate that fluorocarbons will lose one half of this market to not-in-kind replacements, such as carbon dioxide, water, and pentane isomers. In North America, growth potential in the refrigerant market looks fairly positive for the next few years, and the fluoropolymer precursors market will continue to display solid growth. In Europe and Japan, however, concerns about the global warming potential of HFCs are causing the growth of non-HFC refrigerants, and fluorocarbon demand is expected to experience a negative growth rate (Will 2004). It is difficult to forecast how these mixed factors will affect fluorspar consumption. A factor to consider is that many of the replacement HFCs use more fluorspar than the CFCs or HCFCs being replaced. Overall, the North American outlook for HF demand during the next several years is for slow growth of maybe 1% per year.

Worldwide aluminum consumption is expected to increase by 1% to 3% per year during the next few years, and consumption of aluminum fluoride (AlF_3) should mirror this forecast. The strongest growth is expected in China and the Commonwealth of Independent States where the largest increases in aluminum production are expected, and where there are high consumption rates because of the continued use of older smelters. The small increase in AlF_3 consumption is expected to be met by output from fluorspar rather than fluorosilicic acid.

Growth is expected in the cement market. This market has been growing in Mexico, Central America, and South America, and metspar suppliers are hoping to duplicate such growth in Canada and the United States.

What may truly roil world fluorspar and fluorochemical markets is the emerging fluorochemicals industry in China. For the past decade, China has been the world's largest fluorspar exporter but has consumed a relatively small amount of fluorspar (mostly metallurgical and submetallurgical grades) for domestic use. This has now changed, and China is exporting less fluorspar and is actually exporting HF and lesser amounts of downstream fluorochemicals (aluminum fluoride, cryolite, fluorocarbons, etc.). Fluorochemical exports are expected to increase dramatically in the next few years. The only factor that may slow these exports is the growing demand for the same chemicals by the domestic market in China. China's aluminum industry has been growing at a rapid pace, and this requires increasing amounts of aluminum fluoride and cryolite. Fluorocarbon demand in China has increased to the extent that it may already be the largest air-conditioning market in the world. In the near term, these changes mean that other fluorspar-producing countries may find greater demand (and be able to charge higher prices) for their product as China continues to reduce its exports. In the longer term, HF and fluorochemicals plants outside of China may be unable to compete with Chinese exports and be forced to close as Chinese exports increase (Miller 2001, 2002, 2003).

Garnet

R. Randolph Rapp

Garnet refers to a group of similar complex silicates that crystallize as rather dense, tough minerals in the isometric system. Because of the relative hardness and abundance in nature of some garnets, ancient humans used them as an abrasive material. And the deep red color of common garnet created a demand for the mineral as a semi-precious gemstone, an important niche that garnet continues to fill. Today, two members of the garnet group are used as industrial abrasives and in specialized uses as a water filtration medium.

GEOLOGY

Mineralogy

The general formula $A_3B_2(SiO_4)_3$ defines the garnet group. The most common elements filling the “A” position include calcium, magnesium, ferrous iron, or manganese. The “B” position is filled with aluminum, ferric iron or, rarely, by chromium or titanium. Although the crystal structure allows for an almost infinite number of garnet species to form, in reality, only a half dozen or so garnet minerals are commonly found in nature, and only two or three have economic significance.

Table 1 illustrates the most common garnet varieties, their chemical formulas, and some physical characteristics of each.

Between them, almandine and pyrope form a solid-state solution series. Similar series are found—at least on a theoretical basis—throughout the garnet group. Evidence from field analyses, however, suggests that “pure” examples of any of the garnets are extremely rare.

Of the minerals listed in Table 1, only the almandine–pyrope and the andradite–grossular series are common in nature. Minerals of the former series constitute nearly all of the garnet mined for industrial applications. Locally, smaller quantities of andradite are produced for select markets.

Hardness and specific gravity are the key physical properties that create utility for garnet grains and powders in industrial applications.

Modes of Deposition and Occurrence

Members of the pyrope–almandine–spessartine solid solution (the pyrope series) are common accessory minerals in acid igneous and metamorphic rocks in nearly all ancient terranes worldwide. Garnetiferous schists and gneisses are abundant in the cratonic cores and surrounding deformed belts. The garnet minerals occur as discrete grains scattered throughout the host formations and also

Table 1. Garnet types and properties

Mineral	Formula	Color	Mohs Hardness	Specific Gravity
Pyrope	$3MgO \cdot Al_2O_3 \cdot 3SiO_2$	Deep red	6.5–7.5	3.5–3.8
Almandine	$3FeO \cdot Al_2O_3 \cdot 3SiO_2$	Dark red/brown	7.5+	3.9–4.2
Spessartine	$3MnO \cdot Al_2O_3 \cdot 3SiO_2$	Brownish red	7.0–7.5	4.1–4.3
Uvarovite	$3CaO \cdot Cr_2O_3 \cdot 3SiO_2$	Green	7.5	3.4–3.5
Grossular	$3CaO \cdot Al_2O_3 \cdot 3SiO_2$	Pale green	7.0	3.5–3.7
Andradite	$3CaO \cdot Fe_2O_3 \cdot 3SiO_2$	Brownish green	6.5–7.0	3.7–3.8

occur as associated veins and pod-like masses. The hardness and resistance to chemical attack ensure that the garnet crystals survive the erosional process and are concentrated with other heavy minerals in stream placers, or in marine bar and strand deposits.

Members of the grossular–andradite solid solution (the ugrandite series) are enriched in calcium and often are formed as a result of contact or regional metamorphism of limestone-bearing terranes. The most important such occurrences are contact skarn deposits in which many sulfide mining districts are found. The garnet minerals in skarn deposits often crystallize as platy replacement bodies; discrete crystal forms are less common than in the pyrope–almandine deposits. Although concentrated in very large deposits, the lack of markets for andradite and grossular limits production to a few isolated locations, usually as a by-product of other mining operations.

Distribution of Major Deposits

In the United States pyrope–almandine garnet is found in many locations where older crystalline and metamorphic rocks occur; similar deposits are known in many areas of the Canadian Shield. A few of the more important occurrences are described in this section. Most of the garnet produced in North America comes from three unique deposits:

- The Barton Ruby Mountain mine, a hard-rock mine in New York
- The WGI Emerald Creek mine, a stream placer in northern Idaho
- The NYCO wollastonite mine in New York, where andradite is produced as a by-product

Each location serves a different market, and the relative value of the garnet production cannot be compared on a tonnage basis. In recent

years, domestic production in the United States and Canada has been supplemented by imports from Australia, India, and, to a lesser extent, South Africa and China. The increased use of imports largely reflects the economics of mining and transportation rather than insufficient domestic reserves.

United States

California. Large tailings, rich in andradite, are found in the tungsten mining areas on the eastern Sierra front. Skarn-type occurrences are common, but none were developed successfully.

Maine. A high-grade deposit of almandine garnet is located near the town of Rangely, in western Maine. The host rock is probably a granulite (andesine plagioclase with a little quartz and biotite) that locally contains more than 50% garnet crystals. Reserves are likely to exceed several million tons, but commercial development has stalled because of concerns over quartz content in the deposit and the availability of lower-cost resources elsewhere.

New York. The Barton Mines Company operates a well-established hard-rock mine on Ruby Mountain in Warren County. This area is famous for the size and purity of the pyrope-almandine crystals found in metamorphic and igneous rocks there. Many of the garnet crystals have a reaction rim of black hornblende, giving the rock an unusual appearance.

Garnet from the Barton operation exhibits a strong laminar pattern that allows the grains to fracture along predictable planes, a trait that improves performance in certain abrasives' applications.

Similar local concentrations of almandine occur throughout the region, but development is hindered because of their location in Adirondack Park and because of high operating costs relative to other garnet deposits.

Less than 100 miles (167 km) northeast of Ruby Mountain, the NYCO mine produces andradite as a by-product of high-quality wollastonite, which is used in plastics and other applications. Limited quantities of the andradite are used as a high-density water filtration medium.

Idaho. The Emerald Creek mine in Fernwood is located about 90 miles (150 km) southeast of Spokane, Washington. Under various owners for nearly 40 years, the mine currently is owned by WGI Heavy Minerals Inc.

Almandine garnet is eroded from a thick mica schist in the nearby highlands. Mountain streams transport, concentrate, and deposit the garnet in placer gravels, which average 1.0 to 1.5 m in thickness and average 10% to 15% garnet by weight.

Montana. Several alluvial andradite deposits have been identified in the Ruby River drainage system near Dillon. Archean schists and gneisses in the Tobacco Root and Greenhorn mountains are the source rocks for the garnet. At Alder Gulch, garnet has been recovered from local gold-mine tailings. The garnet-bearing alluvium is about 10 m thick and has a garnet content of less than 5%.

When lower-cost imports from India and Australia became available, the Montana deposits suffered in the marketplace, and none are currently active.

Southwestern United States. Andradite garnet associated with local skarn deposits is found in a number of mining districts in the western states. One deposit near Las Vegas, Nevada, was tested for possible use in Southern California markets, and a deposit near Carlsbad, New Mexico, currently is being evaluated. The andradite deposits generally are not well suited to supply garnet for abrasive blasting, and they must compete with lower-cost imports in many locations.

Eastern United States. Almandine garnet occurrences are found throughout the eastern United States in crystalline and meta-

morphic regions along regional orogenic belts and mountains. Several of these were in production briefly in the late 19th and early 20th centuries, but none currently appear to have potential. Most of these occurrences are described in local "rock hound" literature.

Australia

Australia is the world's leading garnet producer. At the GMA Garnet Ltd. mine, located about 100 km north of the West Australia port city of Geraldton, the deposit is an almandine-rich, elevated beach bar or strand line occurrence amenable to low-cost, open-pit mining methods. An associated dune field also is enriched in garnet. The GMA deposit is the result of two cycles of erosion and deposition, and, as a result, the garnet grains are well rounded and well sorted—traits that make the garnet especially attractive in many markets.

Small amounts of almandine are produced as a by-product at the Cable Sands heavy minerals operation in Western Australia. Several other alluvial and hard-rock garnet occurrences are known in Australia, but none are currently in operation.

South Africa

Fine-grained alluvial almandine garnet is produced as a by-product at the Richards Bay heavy minerals complex on the northeastern coast. Although somewhat limited in available size grades, the garnet is suitable for some markets and is exported to Europe.

Canada

Canada contains well over 100 known garnet occurrences, but none of these are in commercial operation because of their low grade and anticipated high mining costs. Nonetheless, several continue to be reevaluated. Chief among these are the following:

- Hutton Strand—a deposit in extreme northern Labrador, where almandine concentrations in beach terrace deposits are similar to deposits in India and Australia.
- Crystal Peak—an andradite deposit in British Columbia where a very high grade, large deposit has been isolated.
- Stralick—an almandine-rich metasomatic structure located near Sudbury. Its low grade has restricted commercial development.
- Mattawa—although several almandine deposits are located in the Mattawan Township, low grades and the high cost of hard-rock mining preclude development.

India

Almandine is a common constituent of both the granitic rocks of the interior highlands and of the heavy mineral beach and stream deposits found along the southern and eastern coasts. India has become a major world supplier of garnet for international markets because of its low production costs and its easy access to marine transport. Major producers include the following:

- V.V. Mineral—Tamil Nadu State
- Transworld Garnet—Tamil Nadu State and Andhra Pradesh State
- Beach Minerals—Tamil Nadu State
- Indian Rare Earths—Tamil Nadu State

China

China apparently has significant reserves of almandine garnet, but all of the deposits discovered to date have been hard rock in nature. While low labor costs benefit the Chinese producers, the limited marketability of hard-rock garnet and the high cost of inland and distant ocean transport have restricted access to commercial markets.

Europe

Several garnet deposits have been evaluated over the years, including several small alluvial deposits in southwestern Europe and several hard-rock deposits in northern and eastern Europe. As of this writing, there are no active deposits on the European continent.

EXPLORATION AND DEVELOPMENT

Almandine–pyrope garnet is among the most common accessory mineral found in acidic igneous terranes and in common metamorphic and metasedimentary rock assemblages. Its high specific gravity, hardness, and resistance to both chemical and physical attack ensure that garnet grains survive even the most energetic geologic environments to form recognizable alluvial concentrations. The durability of the grain makes it a useful indicator mineral for other minerals (e.g., diamonds).

Exploration for new almandine–pyrope garnet follows the usual pattern of terrane recognition based on general geological characteristics associated with acidic igneous and metamorphic rocks—and the presence of the minerals themselves. Standard techniques of stream sediment sampling for heavy mineral concentrations and geologic mapping are important. In addition, areas containing garnet and having good access are well documented because of their long history of garnet production both as a natural abrasive and as an attractive gemstone.

Exploration for andradite and grossular garnet has taken a different route. Prospectors unfamiliar with the demands of the marketplace for the almandine–pyrope varieties have explored for andradite bodies in known areas of skarn-type mineralization, and so most “new” andradite deposits are actually tailings piles from older mining operations. The only significant andradite production in North America is a by-product at the NYCO wollastonite mine in New York, where a portion of the output is sold to a niche filtration market.

Development programs typically involve delineation of sufficient resources to justify acquisition of mineral title and mining rights and anticipated capital spending. Sampling programs designed to ensure grade quality and to determine the dimensions of the deposit are critical; they are usually site specific and are a response to the market. The development activities of a small producer operating on a beach in southern India, therefore, will differ radically from those of a large integrated heavy minerals producer operating in Western Australia.

It is a common requirement for operators to produce bulk samples for commercial testing and evaluation prior to finalizing mine planning and processing design. In some cases, bulk samples may exceed several thousand tons. Development plans also include the creation of channels for sales and distribution.

MINING AND PROCESSING

Mining methods for the extraction of garnet vary depending on the geologic environments responsible for the host rock. At hard-rock locations, such as the Barton mine in northern New York, open-pit methods have been employed for decades. In China, hard-rock mining may consist of more primitive methods including hand mining.

Garnets are extracted and processed more easily from alluvial deposits. For example, at the Emerald Creek mine in Idaho, garnet is recovered from stream gravels from slots cut by backhoes or small draglines. The stream gravels are passed through a tramnel to reject the oversize, and garnet is concentrated on large wet-jigging tables. The garnet is then shipped to the mill for final processing and packaging.

Beach deposits, such as those mined in Western Australia and in southern India, lend themselves to low-cost earth-moving techniques using scrapers and bulldozers to cut and excavate benches

parallel to the trend of the beach and/or bar deposit. Because manual labor remains central to the operator's community responsibility in India, mechanized mining provides only a portion of the mine activity there.

In general, processing involves separation of the heavier garnet from lighter gangue minerals and the further separation of garnet into discrete size classes designed to meet the needs of specific markets. Following crushing (which is determined by the nature of the specific deposit or the market served), ores typically are washed to segregate material by specific gravity. Most operators employ traditional spiral classifiers for this step, some in conjunction with hydrosizers. At least one company uses flotation methods for the separation of garnet from heavy nonmagnetic fractions. Concentrates are dried and then sorted by both high-intensity magnetic and electrostatic separators. One producer that markets very fine grades for precision grinding and polishing markets also relies on wet-separation techniques for quality control. Final separation yields a product exceeding 95% garnet minerals, which usually contains less than 0.5% quartz by weight. The final production step is dry screening and classifying into marketable sizes, then packaging for sales and distribution.

GARNET MARKETS AND TECHNICAL CONSIDERATIONS

The market for almandine–pyrope-type garnet for use in abrasives is probably thousands of years old. In ancient times, garnet is thought to have been substituted for emery (corundum), and its unique physical properties established it as the abrasive of choice for certain precision applications. These factors led to the development of a “high end” specialized abrasives business, which was served by a few well-established suppliers that shipped product to markets throughout the world.

Some of these market characteristics are still in place today, but the demands of garnet markets have evolved in several directions. The markets of the 21st century bear little resemblance to those of the 20th, and the 1990s saw profound changes that continue to shape the production and sales of garnet. Because few deposits contain either the grain sizes or other characteristics necessary to serve all markets efficiently, production has become segmented. Overdevelopment in the 1990s created oversupply in many markets; it most likely will take many years for market demand to catch up to worldwide production capabilities.

For the purpose of this review, garnet markets can be divided into two broad categories: traditional high-end, technical applications that formed the early basis of the industry; and less technical, higher-volume markets for loose-grain material that forms the basis of the current market. Each is described in the next two sections.

Technical Uses

Coated and bonded abrasives (e.g., sandpaper and grinding wheels) using angular crushed grains of almandine have been in the market for generations. With the advent of harder, more aggressive media (e.g., aluminum oxide), these products have evolved into narrower, more specialized applications, but they retain an important niche in the manufacturing and woodworking sectors. In the late 1800s, the New York almandine products opened up this market and today continue to dominate the supply. The unique ability of New York garnet to fracture and break along parallel parting planes gives it an advantage over competing materials.

Finely crushed and pulverized almandine is processed and precisely sized to make optical glass polishing and lapping compounds. Historically, this market sector also was dominated by material from the New York deposits, but as television picture-tube manufacturing has grown in the Far East, almandine powder plants were established in Australia, India, and China. The advent of flat-screen TVs

has altered this market significantly. In recent years, many traditional TV plants have closed, and, as a result, the garnet suppliers have closed or restricted operations accordingly.

Demand from the coated and bonded abrasives market is expected to remain flat or to decrease slightly in coming years. And, as the use of flat screens for TVs becomes the staple, the demand for garnet powders is expected to continue its decline.

Loose-Grain Applications

Almandine–pyrope garnet currently fills three loose-grain applications: (1) abrasive blast media, (2) abrasive grains for water-jet cutting, and (3) a high-density medium in water filtration.

Abrasive Blast Media

In abrasive blast cleaning (i.e., sandblasting), grains of abrasives are accelerated under pressure to impact and clean a surface prior to application of a protective coating system. Abrasive blasting is generally thought to be the most efficient and cost-effective means of preparing surfaces prior to painting. The process yields a clean, roughened surface to which coatings will bond.

The physical traits of garnet are the basis for its use as a blasting abrasive in certain markets. The characteristics of the selected abrasive—grain size, shape, hardness, mass, chemical content, and even color—all have a bearing on efficiency and performance. Specific jobs may call for relatively large angular grains that can cut through thick coatings and layers of rust. Other jobs, such as the removal of mill scale on newly manufactured steel, require the use of hard, durable grains that are more rounded and smaller in particle size.

Abrasive blasting is a means of transferring kinetic energy from the abrasive to the surface being cleaned. As such, the specific gravity—the mass, in this case—is the most important characteristic of garnet. Heavier blast media carry more energy than lighter media and therefore should create a superior blasting agent. The specific gravity, however, must be balanced with the air stream's ability to accelerate the abrasive. Low-pressure air streams or media that are too heavy will not produce the desired effect. Garnet's relatively high specific gravity (4.0) has significant kinetic energy but makes it too heavy for low-pressure blasting.

Lastly, abrasive blasting can be a disruptive and dusty process. Some minerals used as alternative blast media have known associated health risks for the operator and create potential environmental problems on disposal. Because most garnet abrasives probably contain no heavy metals and less than 0.5% free silica, this is beneficial in the abrasives blasting market and has aided in the increased use of garnet blasting media over the past decade.

When properly prepared, the use of almandine–pyrope grains can overcome most of the apparent problems associated with other blasting media. This mineral series is hard enough to meet most needs and durable enough to minimize problems with dust at the blasting site. In North America, where low-cost silica sand is still the most widely used blasting medium, garnet has earned a small share of the market. Higher costs—three to four times more than competing materials—has prevented greater market penetration, so a sophisticated cost/performance analysis must be completed in most cases. Although many blasting contractors do not recognize the value of garnet, in countries where silica sand is banned or restricted, garnet has earned a more significant market share.

Use of andradite and grossular garnet as blasting media is rare. The less durable nature of andradite, because of its crystal structure, causes rapid breakdown and dusty conditions during blasting. It offers little technical advantage over the use of lower-cost media.

Abrasive Grains for Water-Jet Cutting

Water-jet cutting is the process of combining water under ultrahigh pressure with entrained garnet grains to cut a wide range of materials ranging from soft leather and fabric to hard steel, titanium, and other metals. It is possible to carve extremely complex shapes with computer-assisted cutter control. Water is first focused into a tight, restricted stream (usually about 0.010 in. [0.25 mm] in diameter) by passing it through a ruby or diamond orifice. The stream then passes through a mixing chamber and focusing tube. Although garnet is introduced in the mixing chamber where it begins to mix with the water stream, most mixing occurs in the focusing tube. The garnet-laden water stream exits the tube at very high velocity and is directed at the item to be cut. Almandine–pyrope garnet is excellent for this application as it strikes the necessary balance between cutting productivity and equipment wear.

Development of the water-jet market began slowly in the 1980s and early 1990s, but it has grown at a faster rate in the past 15 years. Future growth is expected to remain steady as use of this technology expands in existing areas and enters new applications that require an entrained flow of abrasives (garnet) in the water stream to cut metal, plastics, and glass. Abrasive water-jet cutting provides a tool for manufacturers faced with the task of cutting new materials such as composites and sandwiched materials that presented special machining problems in the past. Water-jet cutting also allows for flexibility and eliminates the need for flame cutting. For example, when cutting fragile materials or intricate patterns in a work piece, abrasive water-jet cutting significantly decreases the amount of distortion or breakage.

High-Density Medium in Water Filtration

Water filtration is the third market segment for loose-grain garnet. In this application, garnet—either almandine–pyrope or andradite–grossular—replaces common sand or gravel in the filter system. Sand filters trap and collect particulate matter in natural, municipal, or process waters. The use of garnet in the system provides a high-density layer that can be maintained after routine system backwashing. The relative high density of garnet allows for more rapid filtration rates and for more efficient backwashing. In addition, the durability of the garnet permits an extended life-span for the filter bed.

Besides its high density, the value of the garnet in water filtration lies in its availability in specially graded gravels, its resistance to chemical attack, and its tenacious nature. The disadvantage of garnet as a filtration medium is its higher installation cost when compared with lower-cost silica sand. Highly cyclical, this market application for garnet is presently considered to be flat. In addition, there is concern that new filtration techniques will erode the future demand for garnet in this market.

Standards for Garnet Applications

Minimum quality and technical standards are established for each garnet application. Although there are no national standards for loose-grain abrasives used in blast cleaning and water-jet cutting, the marketplace efficiently eliminates materials that perform poorly. Efforts to impose narrow screening limits on garnet producers have failed because—unlike manufactured products—mine operators are limited by the nature of the deposits. For example, beach sand deposits cannot provide coarse, angular garnet if none is present in the natural sand deposit.

Nonetheless, the industry has established some specifications and guidelines that affect the producers. Some of these are the following:

- California Air Resources Board—certifies blasting abrasives (CARB, undated)

- MIL-A-22262B—U.S. military abrasive specification (DOD 1996)
- SSPC ABM-1—industry trade group specification (SSPC 1989)
- ANSI B74—U.S. Coated Abrasive Standard (ANSI 1992)
- ISO 9001—International Organization for Standardization quality control protocol (ISO 2000)
- B100-01—American Water Works Association filter standard (AWWA 2001)

Most of these do not prevent a mining company from entering and serving targeted markets. Because of the inherent nature (or geological character) of the deposit, however, some mines are better suited to meet certain specifications. For example, the military specification for blasting abrasives imposes a limit of 1.0% crystalline silica (quartz), but this generally is not a problem for garnet producers.

Table 2 shows the size ranges of the most important garnet grades. Because there are no industry-wide standards, the ranges are subject to the capabilities and interests of individual producers.

PRICING AND FUTURE TRENDS

Over the last decade, garnet prices have declined in all markets. Inflation and increased logistics costs have contributed further to reduced returns for producers. This is the result of at least two economic factors. First and foremost, supply has grown at a much faster rate than has demand. Second, oversupply of fine grades has stimulated discounting in attempts to equalize demand at individual mine sites. As of this writing, this strategy has failed. Pricing in each market varies widely depending on the type of garnet, the grade required, the amount ordered and shipped, and the type of packaging. The estimated values of several key garnet products around the world (in U.S. dollars, free on board [f.o.b.] bagged) are as follows: North America, \$125 to \$600; India, \$60 to \$120; and Australia, \$90 to \$145.

Pricing at the user location is affected further by transportation costs, warehousing and distribution expenses, and premium pricing for small-lot orders. Real price increases, which were forecast in the 1990s, will continue to be delayed until excess capacity is absorbed or a new use for garnet causes a significant change in the pattern of demand.

Demand for garnet in both blasting and water-jet cutting was one such benchmark event. The next possible surge in demand for garnet could come from the tightening of environmental regulations and industrial hygiene requirements in the United States and Canada. Concerned groups in both countries have questioned the widespread use of metallurgical slags as abrasives. Trace metals found in these slags may constitute an environmental and/or health risk. On the other hand, slags continue to be the second largest provider of blasting abrasives in the United States—right behind silica sand. Thus, it is highly unlikely that any legislation of consequence will be passed in the foreseeable future. In addition, some U.S. authorities have considered changing regulations governing the allowable exposure limits for crystalline silica in the workplace. For further discussion on the controversy and regulations pertaining to respirable silica dust, refer to the chapter on Industrial Sand and Sandstone.

With increased defense spending, blast cleaning in shipbuilding and aircraft manufacturing is predicted to increase over the next few years, as is oil-drilling pipe cleaning, the result of more oil-field exploration drilling.

Garnet markets likely will continue to exhibit the basic two-tiered quality classification that has developed over the last 15 years. Applications demanding superior levels of product quality will continue to find material available at premium price levels. Those

Table 2. Size ranges of selected grades of garnet

Use	U.S. Mesh	Micrometers
Blast Media		
X-Coarse	16 × 20	1,200/840
Coarse	20 × 40	840/420
Medium	30 × 60	600/250
Fine	60 × 100	250/150
Jet-Cutting Media		
Coarse—Demolition	40 × 60	420/250
Standard	60 × 80	250/180
Fine	80 × 100	180/150
Filter Media		
Coarse	12 × 20	1,700/840
Fine	40 × 60	420/250
Other Uses		
Grains	36 through 280	
Powders	320 through 1,600	

applications that are less demanding will be served by the lower-cost, less technical products.

ALTERNATIVE MATERIALS AND MINERALS

Garnet is a substitute for other minerals or manufactured products in key areas of application. In abrasive blasting, it is a higher-cost/high-performance substitute for silica sand and slag. Manufactured abrasives such as aluminum oxide and steel grit offer the user alternative media at higher costs, but at levels of cutting productivity superior to those of silica sand and slag or at greatly reduced rates of material consumption through recycling. The user is presented with a wide range—if not confusing array—of choices. In the U.S. market, the mineral staurolite is yet a third choice. Produced as a by-product at titanium mineral mines in northern Florida, fine-grained aluvial staurolite is packaged and marketed aggressively as a low-cost (<US\$100 f.o.b. per ton) alternative to silica sand and slag. The small grain size makes it ideal for preparation of new steel but limits its application in more rigorous maintenance painting programs.

In water filtration, garnet is a substitute for common silica sand and gravel. Its use as a high-density mineral can be mimicked by any mineral having a sufficiently high specific gravity. Other products such as specular hematite, magnetite, ilmenite, plastics, and iron slag are used with varying success.

Almandine-pyrope garnet has proven to be the best choice for use as a water-jet cutting medium. It is hard enough (Mohs hardness of 7.5+) to ensure the efficient cutting of most industrial metals, but not hard enough to cause significant levels of equipment wear. Its specific gravity seems just right for this application while still providing maximum energy transfer. Also, producers have worked hard to meet the specifications for the water-jetting application in providing clean, well-graded products around the world. Nonetheless, research for an effective substitute for garnet is ongoing. Although media such as aluminum oxide or other manufactured “super” abrasives can increase cutting speed greatly, this is more than offset by increased component wear. Materials and forming sciences are working together to seek a superior tube construction that will allow the use of these more aggressive abrasives. If this is accomplished, it will have significant consequences for garnet suppliers.

Garnet's other specialized use as coated abrasives for fine woodworking and finished polishing powders and lapping compounds seems to be a stable, if somewhat mature, market. Quartz

sand, silicon carbide, and fused aluminum oxide are alternatives to garnet in these applications.

ACKNOWLEDGMENT

This chapter draws heavily on the previous work of Gordon T. Austin (1994) of the former U.S. Bureau of Mines. His contributions are gratefully acknowledged.

Gilsonite

Bryce T. Tripp and Earl R. White

INTRODUCTION

Gilsonite, a naturally occurring solid hydrocarbon of the asphaltite group, is found in commercial quantities in the Uinta Basin of northeastern Utah, in Uintah and Duchesne counties. Gilsonite occurs in a subparallel set of straight, linearly continuous, vertical veins in a northwest-southeast trending zone approximately 100 km long by 50 km wide (Figure 1). The veins are an integral part of the hydrocarbon-rich Uinta Basin, which also contains oil shale, coal, tar sand, and other solid hydrocarbons, including wurtzilite, tabbyite, and ozokerite.

Definitions

Gilsonite occurs in disseminated blebs and in dikes (veins), sills, and fracture fillings, often in association with oil shale or bituminous deposits (tar sands). Gilsonite has a dull, black, coal-like appearance on weathered surfaces and a shiny, black, obsidian-like appearance (Figure 2) on a fresh, conchoidal to hackly fracture surface. A small amount of Gilsonite in deep parts of some veins is in a semisolid state or in the form of a liquid ooze. Gilsonite solidifies with increased oxidation of its organic compounds and loss of hydrogen (Hunt 1963). Industry at one time defined three major subdivisions of Gilsonite based on appearance and fusing temperature: selects, seconds, and jet. Selects material is very shiny, fuses from 149°C to 168°C, and tends to occur in centers of veins. Seconds are somewhat duller than selects, fuse from 152°C to 183°C, and tend to occur along vein margins, sometimes with a columnar-jointed, “pe ncillated” texture. Pe ncillated texture forms at right angles to vein walls and penetrates about 15 cm into the ore. Gilsonite also has flaky or scaly texture in some localities. A third, unusual variety called *jet Gilsonite* has a brilliantly shiny surface, is bluish black, and fuses from 199°C to 230°C (Abraham 1960). It was found only in the Cowboy vein. Gilsonite is now classified by fusing temperature in to five ranges, which are used in different applications and sell for different prices. Gilsonite from different veins or different parts of veins is sometimes mixed to achieve a product with a specific fusing temperature range.

Gilsonite was named after Samuel H. Gilson. He was not one of the original discoverers of Gilsonite, but became linked to the material through his enthusiastic search for its uses and markets, and local people began referring to the material as Gilsonite rather than by its scientific name, *uintahite* (Kretchman 1957; Covington 1964). The name *Gilsonite* was further solidified in common usage when a mining company adopted and trademarked the name.

In the late 1800s, people were uncertain about the exact nature of Gilsonite and whether it was asphaltum, coal, or mineral wax. Samples were shipped to several scientists during the 1860s to early 1880s for examination. Henry Wurtz (1869) described a sample in the Columbia College School of Mines collection and noted the similarity of this material to the grahamite that occurs in dikes in Ritchie County, West Virginia. Blake (1890) examined this same sample and determined it to be *uintahite*, an asphaltite that he had described in an earlier scientific paper (Blake 1885).

Properties

Physical and chemical characteristics of Gilsonite (Table 1) are important both for differentiating among asphaltites and determining its industrial applications.

Hydrocarbon Classification

Gilsonite is classified as a member of the asphaltite group of hydrocarbon bitumens. A wide range of naturally occurring solid hydrocarbons are somewhat similar in appearance, occurrence, and properties. Scientists began describing these materials and developing schemes to differentiate between them more than 100 years ago. Herbert Abraham (1960) developed a systematic classification scheme for hydrocarbons based on physical and chemical characteristics such as solubility, physical state (solid or liquid), fusibility, and oxygen content. Hunt (1963) slightly modified Abraham’s classification system. King, Goodspeed, and Montgomery (1963) devised a classification scheme starting with the geologic origin of the hydrocarbon. Hunt (1979) combined aspects of the Abraham classification and the King, Goodspeed, and Montgomery classification, deleted petroleum from the scheme, and subdivided some of the hydrocarbons based on their hydrogen-to-carbon ratios (Figure 3). Other proposed variations have been published in Rogers, McAlary, and Bailey (1974), Jacob (1983), Curiale (1986), and Cornelius (1987). Curiale (1986) discounted the predominantly physical/chemical approach and emphasized classification by molecular and bulk maturation data. Jacob (1983) emphasized the use of petrographic data in classifying solid bitumens. Hunt’s (1963) classification scheme is commonly accepted and is easy to apply using basic laboratory test data.

Development History

Crawford (1957) and Remington (1959) carefully summarized the fragmentary early history of Gilsonite discovery and development;

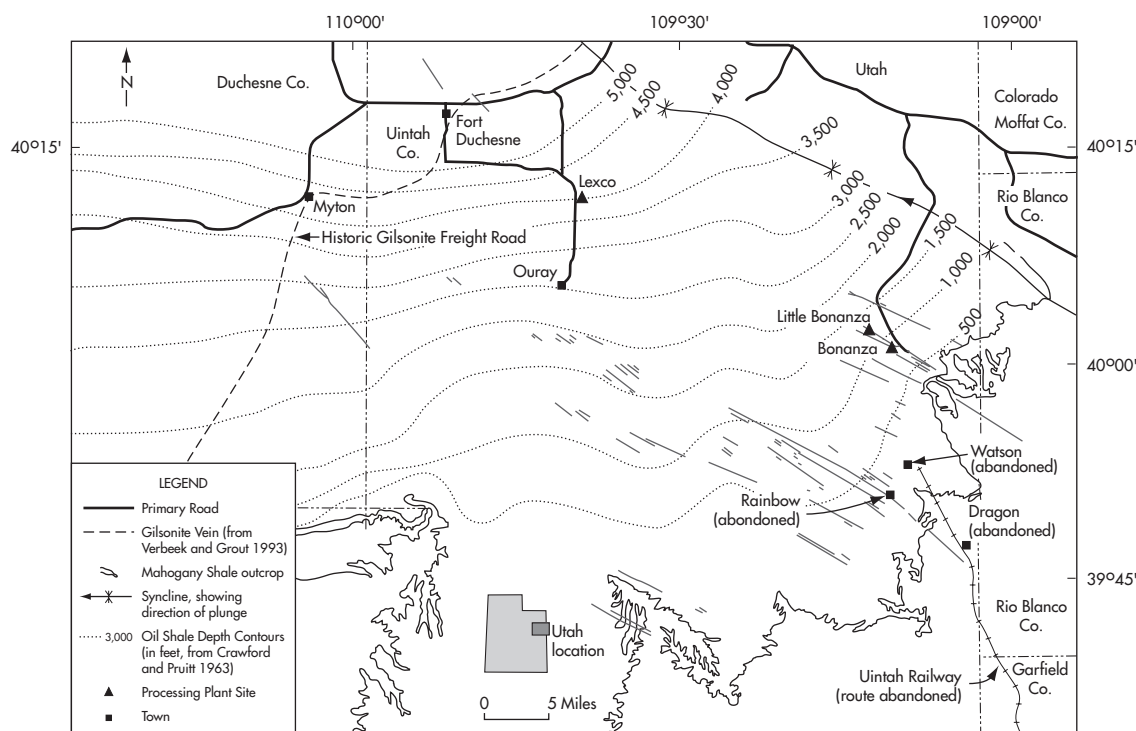

Figure 1. Gilsonite vein locations, industry facilities, and some geologic information for the Gilsonite field, Uinta Basin, Utah

Courtesy of AGC.

Figure 2. Sample showing luster and fracture of an unweathered Gilsonite sample (about 12 cm in diameter)

the following information is largely derived from their reports. Ute and other Native American tribes knew about the Uinta Basin Gilsonite and possibly used this material, but the first documented use of Gilsonite was in 1868 by John Kelly at the U.S. government Whiterocks Indian Agency. Kelly, the agency blacksmith, asked local Native Americans to help him find coal for his forge; the Native Americans collected Gilsonite, probably from the nearby Carbon vein, and brought it to him. When added to the forge, the flaming, molten Gilsonite ran out of the forge and nearly burned down the building (Remington 1959).

Though many prospectors were involved in the early discovery of Gilsonite veins, two individuals deserved the most credit for the early development of a Gilsonite industry. Samuel H. Gilson and Bert Seaboldt independently became interested in Gilsonite in 1885 and 1886, respectively. They formed a partnership in 1886 with other Utah business and mining entrepreneurs, and then incorporated on June 11, 1886, to develop seven mining claims on the Carbon vein that Seaboldt had staked on January 9, 1886. Both Gilson and Seaboldt were enthusiastic promoters of this hydrocarbon material, but Samuel Gilson (a flamboyant sheriff, rancher, horse trader, and inventor) captured the imagination of local residents while promoting the material, so they jokingly called the material Gilsonite. The name *Gilsonite* became even more established when Gilson, as a jest, offered his new partners one dollar if they would name the material and company after him. They agreed and named the company the Gilsonite Manufacturing Company and trademarked the name Gilsonite for the material.

An impediment to further development was that the claims were located on Ute tribal lands and, therefore, were technically invalid. Seaboldt and partners lobbied the U.S. Congress who agreed to remove the Carbon vein from the reservation if the Native Americans would agree to sell the land. In September 1888, the Utes ratified an agreement relinquishing 2,800 ha of land around the Carbon vein in exchange for a payment of \$49/ha. The Gilsonite Manufacturing Company mined and shipped about 2,700 Mt of Gilsonite from the Carbon vein in 1888 that sold for \$88/Mt.

A few years of rapid property consolidation followed, which are well documented by Kretchman (1957) and Crawford (1957). Gilson and partners continued to stake and purchase additional claims. Gilson and Seaboldt also became associated with Charles O. Baxter, a mining engineer from St. Louis, Missouri. Baxter incorporated the St. Louis Gilsonite Company on June 16, 1887,

with Samuel Gilson apparently owning an interest in the company. Baxter and Gilson spent part of 1887 and 1888 staking and purchasing Gilsonite properties; Baxter probably spent about \$115,000 for Gilsonite property in the Duchesne area (Kretchman 1957). During this time, Baxter picked up a substantial land position along the Pariette vein. In 1889, the Anheuser-Busch Company bought out Samuel Gilson's share of the St. Louis Gilsonite Company and changed the name of the company to the Gilson Asphaltum Company (Kretchman 1957). Anheuser-Busch was interested in using Gilsonite for lining beer barrels. The Gilson Asphaltum Company also acquired all the assets of the Gilsonite Manufacturing Company for \$100,000 after September 1889, making the Gilson Asphaltum Company the largest Gilsonite company in the Uinta Basin. Baxter retained Seaboldt and other Gilsonite Manufacturing Company employees as mine operators and renamed the development on the Carbon vein the St. Louis mine.

Many other Gilsonite veins had been discovered in the basin and many were located on Ute tribe lands. Gilsonite prospecting,

among other immigrant infringements on tribal lands, led to armed conflict between Ute tribal members and U.S. Cavalry troops. Company negotiations with the Utes and federal legislation altering tribal land boundaries eventually gave Gilsonite miners clear title to the best Gilsonite veins by 1903 (Kretchman 1957; Covington 1964). The Gilson Asphaltum Company then held the largest Gilsonite resources, a virtual monopoly (Kretchman 1957). Property consolidation and resolution of remaining title conflicts cleared the way for rapid expansion of the industry.

From 1888 to about 1906, Gilsonite mined from the Carbon and Pariette veins was transported 80 to 113 km via horse-drawn wagon over a rough dirt road southwestward to the railroad at Wellington in Carbon County (Covington 1964). The round trip took 10 to 11 days. Freight added \$11 to \$13/Mt (late 1800's dollars) to the total production cost of about \$22/Mt (late 1800's dollars) (Kretchman 1957). The Gilson Asphaltum Company decided to expand production and exploit the much larger veins in the Dragon/Rainbow Area by constructing a narrow-gauge railroad, named the Uintah Railway, from the Dragon mine to the Mack, Colorado, siding on the Denver and Rio Grande Western rail line. Construction of the 85-km-long railroad started on October 5, 1903, and was finished by September 1904 (Kretchman 1957). The railroad traversed rugged country and was noted for steep grades, sharp curves, and many bridges (Bender 1970). The rail line was extended in 1911 to the Rainbow mine and the Watson shipping terminal. The transportation cost of a ton of Gilsonite from Dragon to Mack was \$11/Mt (early 1900's dollars) (Kretchman 1957). The Dragon/Rainbow Area was the major production center for Gilsonite from 1904 to 1935. In 1935 the Gilson Asphaltum Company moved its principal operations north to Bonanza, Utah, and shipped ore by truck via U.S. Highway 40 to the railhead at Craig, Colorado; the Uintah Railway was no longer needed and was abandoned in 1937 (Kretchman 1957). Transportation from Bonanza, Utah, to Craig, Colorado, in 1956 cost \$6/Mt. A plant at Bonanza processed ore primarily from the Bonanza, Cowboy, and other large veins adjacent to the plant. In 1938 the Gilson Asphaltum Company changed its name to Barber Asphalt Company (the predecessor of the Barber Oil Company).

Barber Oil Company sold part ownership in the Gilsonite operation to Standard Oil of California (now ChevronTexaco Corp.) in 1948 (Lewis 1994). The new jointly owned company was named

the American Gilsonite Company (AGC). The new company put renewed effort into a long-term research project to make gasoline and high-purity electrode carbon from Gilsonite (Kretchman 1957). Refinery design problems were solved by 1954, but a lower-cost method to transport the Gilsonite was deemed necessary to make the project feasible. After research and analysis, a 116-km-long slurry pipeline was constructed on the abandoned Uintah Railway right-of-way to a newly built (in August 1957) petroleum refinery at Gilsonite, Colorado (Kretchman 1957). The intended market for gasoline from the refinery was western Colorado, and most of the electrode carbon was intended for the growing aluminum smelting industry of the Pacific Northwest (Henderson 1957). Use of Gilsonite for refinery feedstock greatly expanded production.

In 1957, AGC started mining Gilsonite with water-jet cutters to speed production and prevent Gilsonite dust explosions; Kilborn (1964) describes the hydraulic mining technique in detail. AGC sold the refinery in 1973. Mine production declined from about 360,000 Mtpy to about 54,000 Mtpy because the refinery ceased operation. AGC reemphasized nonfuel uses of Gilsonite, and within 10 years AGC's Gilsonite production expanded to 91,000 Mtpy (Jackson 1985). In 1981, AGC replaced its 30-year-old, 4,500-Mtpm mill. The new \$6-million processing plant was designed to process 9,000 tpm of ore, be more efficient, improve product quality, and meet environmental and safety regulations (Jackson 1985). In January 1981, Chevron bought out Barber Oil's share of the business (Jackson 1985; Hawes 1990). AGC has mined ore from several mines on different veins simultaneously to supply the various grades of Gilsonite specified by customers. Softening or fusing temperature is one of the main criteria in grading Gilsonite. In 1983, AGC mined ore from 11 Gilsonite mines near Bonanza (Shushan 1983). In 1990, AGC operated five mines that yielded ore fusing at 168°C; 183°C; 199°C; 205° to 211°C; and 230°C (Hawes 1990). In 1991, Chevron sold out to Stratford Enterprises Company of Tulsa, Oklahoma (Lewis 1994). AGC is now an independent, publicly held company.

Two smaller companies have recently mined Gilsonite: Ziegler Chemical & Mineral Corporation (Ziegler) and Lexco, Inc. Ziegler, the second-most significant Gilsonite-producing company, was incorporated in 1944 as a New Jersey-based producer of pitches, asphalts, and resins. The company, then known as G.S. Ziegler and Company, purchased Gilsonite from small, independent Gilsonite producers. Ziegler decided to acquire its own Gilsonite properties, and in 1952 purchased the holdings of the Utah Gilsonite Company, which had been in operation since 1920. In 1953, Ziegler purchased some of the property of the American Asphaltum Association (a company formed in 1902 by former stakeholders in the Gilson Asphaltum Company). Ziegler purchased one other independent company during the 1949–1953 period. Ziegler additionally acquired the assets of the Standard Gilsonite Company in 1962 and renamed the combined company the Ziegler Chemical & Mineral Corporation (Lewis 1994; Ziegler 2004). The office and plant of the consolidated operations were located at Little Bonanza, Utah. Ziegler usually had produced less ore than AGC, but in 1994 it produced more than 50% of the Gilsonite mined in the Uinta Basin (Ziegler 2004).

Lexco is a relatively recent entrant into the Gilsonite business. It began operations in 1988. Lexco has a processing plant southeast of Fort Duchesne, in central Uintah County, and has mined Gilsonite from the ITM and Cottonwood mines. As of 2004, Lexco operates the Cottonwood mine, where the vein width averages 91 to 97 cm. It is not currently operating the ITM mine, where the vein width averages 46 cm and was mined in sections as narrow as 36 cm.

RESOURCES AND PRODUCTION

Eldridge (1901) estimated that five major veins in the Uinta Basin contained more than 28 Mt of Gilsonite based on field examination. Dennis (1930) quoted a figure of 45 Mt of original, in-place resource; though he does not indicate a source for this number. Cashion (1964) estimated about 41 Mt of original resource based on his extensive geologic investigations of the Uinta Basin. Neel (1980) estimated that about 4.5 Mt of minable reserves remained in the Uinta Basin, with total remaining resources of 9 to 14 Mt. Some undiscovered, probably smaller veins are likely to be added to the resource base in the future.

Gilsonite production from 1907 to 2002 typically ranged from about 9,000 to 54,000 Mtpy with a spike to 430,000 Mtpy in 1961, during Chevron's Gilsonite mining for refinery feed.

GEOLOGY

Geology of Uinta Basin Gilsonite

Gilsonite veins trend northwest to southeast through fluvial and lacustrine sediments of the Uinta Basin. The veins (Figure 1) are nearly vertical, are subparallel with other veins in the area, and are remarkable for their strike length, vertical extent, and uniformity over long distances. Vein lengths of 5 to 10 km are common. The longest vein, the Black Dragon–Rainbow–Pride of the West vein system, is 39 km long. Vein widths of 0.5 to 1.0 m are common. The widest vein, the Cowboy vein, is up to 5.5 m wide. Vein depths are controlled primarily by the depth to hydrocarbon source beds in the oil-shale zone of the Tertiary middle and upper Green River Formation. The Mahogany zone, a particularly rich part of the oil-shale beds (and a probable source bed for Gilsonite), crops out at the very southeastern end of the Gilsonite vein system, dipping gradually northwestward into the center of the Uinta Basin (Figure 1).

The veins cut across gently dipping strata ranging from early Eocene, primarily fluvial Wasatch Formation to the sequentially overlying fluvial and lacustrine, middle and upper Eocene Green River Formation; the fluvial and lacustrine, late Eocene Uinta Formation; and the fluvial, late Eocene and Oligocene Duchesne River Formation. Some Gilsonite occurs in the Green River Formation below the Mahogany zone and in the underlying Wasatch Formation. Gilsonite extends below the Mahogany at the Cowboy, Black Dragon, and Colorado (also known as the Black Diamond; it is continuous with the Weaver and Wagon Hound) veins at the southeastern end of the Gilsonite field (Pruitt 1961). The Wasatch Formation to Duchesne River Formation stratigraphic section was deposited just before, during, and just after the existence of Lake Uinta in the Uinta Basin. Fluctuations in lake level left a complex record of interfingering fluvial, marginal lacustrine, and open-water lacustrine facies. Oil shale, the petroleum source for the Gilsonite, was deposited in a shallow-water, open-lacustrine depositional setting with abundant algal growth and preservation.

The Uinta Basin is an asymmetrically structural, stratigraphic, and topographic basin. It has a steeply dipping northern flank and a gently dipping southern flank. The Uinta Basin was initiated by west-to-east compressional tectonics of the Cretaceous Sevier Orogeny. The Sevier Orogeny created extensive thrust-related mountains in western Utah and a subsiding foreland basin in eastern Utah. Subsequent early Tertiary Laramide orogenic deformation segmented the Sevier foreland basin into a series of uplifts and basins that included the Uinta Basin. The Uinta Basin is surrounded by the Uinta Mountains to the north, Douglas Creek Arch to the east, Uncompahgre Uplift to the southeast, San Rafael Swell to the southwest, and Wasatch Range to the west.

Origin of Uinta Basin Gilsonite

Geologists have studied and discussed Gilsonite's origin for more than 100 years. Verbeek and Grout (1993) give an interesting summary and critique of the numerous theories. They conclude that Gilsonite is an early derivative from the abundant oil shale in the middle and upper part of the Green River Formation, expelled under the heat and pressure of burial. Studies have demonstrated chemical similarities between oil-shale source beds and Gilsonite (Hunt, Stewart, and Dickey 1954; Hatcher, Meuzelaar, and Urban 1992). Hydrocarbon generation probably created overpressured conditions. Water, expelled under these conditions, hydrofractured the rock in an extensional tectonic setting. Later, viscous Gilsonite generated in the deeper part of the basin was forced upward and laterally along the preexisting fractures, pushing them open.

The idea that the fractures predate Gilsonite emplacement is supported by wall rock mineralization and alteration data. Thin layers of iron oxide and some authigenic quartz crystals commonly coat wall rocks, and iron oxide and chlorite fill wall rock pore space, separating wall rock from the later-emplaced Gilsonite. In some areas, calcite deposits separate wall rock and Gilsonite vein filling (Monson and Parnell 1992). Also, wall rock is often bleached along the veins. Verbeek and Grout (1993) attribute these coatings, pore fillings, and bleaching to the migration of a large volume of water through these fractures before Gilsonite emplacement.

Several types of data support the concept that Gilsonite was forcibly injected. Some Gilsonite occurs as sills, so pressure of emplacement exceeded the lithostatic load. Gilsonite also locally impregnated wall rock typically from a few centimeters up to 1 m in depth (but up to 5.5 m has been reported [Pruitt 1961]), implying high-pressure emplacement. Monson and Parnell (1992) and Verbeek and Grout (1993) studied the structural features of vein walls and found them consistent with emplacement under high pressure rather than passive filling under low pressure.

The idea that Gilsonite was intruded as viscous, plastic material is supported by observed relationships between Gilsonite and wall rock. Most notably, slabs of spalled wall rock often did not fall to the bottom of the vein but were supported in Gilsonite not far below their original point of attachment to the wall rock.

Global Asphaltite Deposits

Large concentrations of high-purity Gilsonite are rare in the earth's crust; the Uinta Basin deposits are by far the most economically significant. Table 2 lists the few other Gilsonite occurrences reported in the literature along with deposits of glance pitch and grahamite, the other two members of the asphaltite group of hydrocarbons. These two other hydrocarbons are listed because they have similar origins; they may occur in the same sedimentary basins; and, in a few applications, glance pitch and grahamite might be blended with Gilsonite or substituted for Gilsonite. Many of the deposits listed in Table 2 are of scientific interest only and have no economic value, or were mined out years ago. Additionally, identification of the asphaltite present at some of these deposits is questionable.

EXPLORATION AND MINING

Exploration and Deposit Evaluation Techniques

All of the veins mined today are considered "old" known veins because they were discovered by prospectors examining and mapping surface exposures. The veins, where exposed, have prominent surface expressions, appear as black straight bands irrespective of topography, and contrast strongly with host rocks of tan sandstone and siltstone. The veins, however, are frequently covered by allu-

vium and colluvium and may be well exposed only on ridges and in drainages, disappearing under valleys, and reappearing on adjacent ridges. Where covered, veins can often be mapped by the presence of weathered Gilsonite flakes, sparse vegetation directly over Gilsonite veins, or evidence of past mining such as the presence of headframes and shafts. The veins are straight and continuous and the regional geology is uncomplicated, making it easy to extrapolate between good exposures. Because Gilsonite is very lightweight, it is easily washed down colluvium-covered slopes, so streaks of Gilsonite float can be offset from actual vein locations by 6 m or more.

Where alluvium or colluvium covering is relatively thick, the usual exploration technique was to project the trend of a vein, and then trench or sink shallow shafts to verify location and determine the extent and quality of the Gilsonite. The current exploration practice involves angle drilling of suspected vein extensions with a truck-mounted drill rig; AGC uses a Longyear 44 rig. Planned mine site locations are core drilled to determine if minable ore exists at various depths. Drilling is important because, in the past, mines had to be abandoned soon after mining started because the ore pinched out. Before a mine begins operations, the shaft location typically is core drilled to various depths; additional drilling generally is completed 122 m along the strike of the vein on both sides of the shaft. Data collected during exploration include mining information such as vein width and wall rock characteristics and also ore quality. Quality characteristics of Gilsonite veins, particularly the melt point, viscosity, and ash content, can change rapidly along strike or with depth. This information is important for mine planning and for determining potential markets for the Gilsonite.

Because Gilsonite veins are almost vertical, it is necessary to position the drill rig at right angles to the trend of the vein and to angle the drill string so that several holes from the same drill pad intersect the vein at various depths. Typical drill intercepts are at vertical depths of 30, 91, 183, and 244 m. The driller completes most exploration drill holes with carbide button bits with a 37/8-in. diameter. When the hole is approximately 15 m from the calculated Gilsonite intercept, the driller switches to a 17/8-in.-diameter core bit to complete the hole. The core is extracted in 1.5-m segments and saved for testing. Drilling several angle holes from the same pad saves time and reduces environmental impacts; the environmental footprint of the site is generally less than 0.1 ha. Minimizing environmental impacts aids the exploration permitting process.

AGC conducted an extensive exploration and development program starting in the early 1970s, which was managed by Chevron geologists. The Rainbow, Little Emma, Eureka, Independent, Bonanza, and Wagon Hound veins were drilled. Almost all drilling was done to verify reserves, which AGC planned to mine five or more years in the future. AGC opened one mine in 2000 on reserves core-drilled in the early 1980s, and then redrilled by AGC in 1998. AGC's current practice is to drill five or six locations per year.

Geochemical and geophysical exploration methods for Gilsonite have yielded mixed results, and so none has become standard procedure. Botbol (1961) collected soil samples along a closely spaced transect across covered extensions of known veins, and then concentrated and measured the Gilsonite in the samples. The data showed that anomalously high Gilsonite content in closely spaced samples matched the expected trend of the veins.

Several questions must be answered to determine whether a Gilsonite vein can be mined:

1. Who has title to the land and minerals? A significant part of the remaining Gilsonite resource is on federal or Native American reservation lands, and leasing can be difficult.

* na = not available.

2. Is the deposit accessible? Some unmined portions of veins are located in very remote parts of the region with concomitant high transportation costs. Additional road construction and improvements may be needed (with associated permitting costs). Trucking costs from mine to processing plant can be high.
3. Is the Gilsonite vein thick enough? The average width of veins mined to date is about 1.8 m, but veins from 46 to 51 cm wide have been mined recently (veins as narrow as 36 cm have been explored).
4. Does the Gilsonite meet minimum grade requirements? The fusing temperature of Gilsonite ore is critical.
5. Is the Gilsonite contaminated with broken wall rock? In some cases, excessive wall rock contamination prevents the mining of some of the vein.

Mining and Transportation

Three companies produced Gilsonite in 2004. AGC produced from six mines on four veins (two on the Eureka, two on the Wagon Hound, one on the Independent, and one on the Bonanza). Multiple mines operate simultaneously to yield material for various uses. Gilsonite from certain mines may meet requirements for specific uses, or different grades of Gilsonite from two or more mines may be blended to meet customer specifications. Mine planning is completed for each year based on business forecasts for four major markets: oil-field uses, foundry applications, asphalt, and inks. Ziegler produced from mines on several veins, and Leeco produced from the Cottonwood mine on the Cottonwood vein.

Early mining consisted of deep trenching along veins by hand using sharp picks, bagging the broken ore in 90-kg cloth bags, and hoisting the ore to the surface using a wooden headframe and horse power or, later, tractor power. Explosives commonly were not used because of the risk of explosion from Gilsonite dust. All Gilsonite produced today from the Uinta Basin is collected by underground mining methods (Figure 4). Mining consists of two major phases: shafts are sunk at regular intervals along the veins, and drifts and

slopes are then extended laterally from the shafts. The surface Gilsonite of the vein is not mined; a surface pillar with a minimum thickness of 9 m is left between shafts.

Mining begins with main shaft development either by hand sinking directly into the ore or by drilling the shaft with a Teton drill rig that has a large-diameter (2.1-m) bit. The method selected depends on the width of the vein at the surface and at depth. Hand sinking is preferred if the vein is at least 0.6 m wide at the surface because it yields saleable Gilsonite. Shaft drilling contaminates the Gilsonite with wall rock; it is, however, sometimes necessary on veins that, on outcrop, are too narrow for hand mining but widen at depth. The Eureka vein outcrops usually are narrow, but the vein widens with depth; therefore, the large-diameter drill is used to develop a shaft down to the depth where the vein is at least 1.2 m wide. Once this width has been encountered, shaft sinking continues by hand. Drilled sections of shafts are usually about 67 m deep. Shafts developed in the ore body are typically 8 m long. All the shaft support equipment, including landings and guide rails, is installed in conjunction with hand sinking. The shaft contains three compartments: two outside compartments contain pipes for the air-lift and compressed air, and a central compartment contains a skip for miners.

Once the main shaft has been developed to a depth where the ore is wide enough for mining and is at least 9 m below the surface, a drift is started in one or both directions from the shaft. These drifts extend 152 to 213 m from the shaft and serve as the escapeway drifts for the initial phase of mining. When the initial drifts are complete, a small escapeway shaft is raised to the surface or is drilled if the distance from the surface to the escapeway drift is more than 15 m. Where the ore width is insufficient to conduct shaft raising or sinking in the vein, an escapeway shaft is drilled to intersect the escapeway drift.

Recently, AGC changed its mining methods by sinking the main shaft to the bottom of the ore deposit, and then developed the initial drifts at this lower level, extracting ore from the bottom to the top of the mine. The major benefit of this method is reduced

Courtesy of AGC.

Figure 4. Schematic cross section through a typical vein Gilsonite mine showing development of underground workings and typical surface facilities

maintenance of the shaft and escapeway. After the ore has been extracted from the lower levels, those portions of the drifts and shaft no longer need to be maintained. If mining is conducted from the top of the mine to the bottom, all drifts and shafts must be maintained for the life of the mine.

In 1963, AGC began using a 1.5-m-diameter drill rig to drill shafts on Gilsonite veins. This prototype reverse-circulation rig used water as a drilling fluid, featured reversible rotation direction, and had an average drilling rate of 9 m/hr in Gilsonite and 0.9 to 1.2 m/hr in sandstone wall rock (Kilborn 1964). AGC currently uses a similar rig with a 2.1-m-diameter bit and an airlift system to remove drill cuttings through the drill stem.

Gilsonite slope mining usually is initiated by developing two drifts, 30 vertical m apart, from the main shaft to the escapeway shafts. Development can take place along strike in both directions from the shaft. Once these drifts are completed, mining begins on the floor of the upper drift downward, creating a 45° slope angle. This slope is extended along the upper drift until the bottom of the slope reaches the lower drift, creating a slope in the ore body, which is approximately 43 m long. Mining progresses from the bottom of the slope, which is the lower drift, to the top of the slope, which is the upper drift. A miner using a chipping hammer cuts a 1.2-m-high bench on the bottom of the slope. The miner then cuts this bench up the 45° incline to the top of the slope. As the ore is cut with the chipping hammer, it slides down the slope and is directed into the

airlift that conveys the ore to the surface. In a 1.5-m-wide vein, each bench mined up slope yields 79 Mt of production. These benches are mined until the slope reaches the escapeway shaft. The remaining triangle of ore is mined from the top to the bottom of the slope so that a straight face of ore is left.

The Gilsonite ore usually is mined using industrial pneumatic chipping hammers that weigh approximately 5.4 kg and are equipped with 30.5-cm-long, hardened steel moils. Compressed air for the chipping hammers comes from a 112-kW air compressor on the surface via a 7.6-cm-diameter steel pipe down the shaft to the working face (Jackson 1985). On occasion, permissible explosives will be used if the ore is particularly hard to mine.

The nearly vertical attitude of Gilsonite veins requires setting mine timbers in the following manner. Mine timbers are placed on 1.5-m centers to provide ground support in Gilsonite mines. The timbers used in the shaft and on working floors are "hitched" into holes approximately 5 cm deep and slightly larger than the diameter of the timber and are locked into these hinges with wooden wedges. With the support resting on the 5-cm-wide rock ledge of the hitch, the timber will remain in place regardless of shrinkage. Timbers that are set only to control the wall rock are not hitched but are placed on 5 × 25 × 30 cm cap boards on each end and then wedged tightly into place.

AGC conveys the mined ore from the shaft, drift, or slope by means of an airlift system (made possible because of the relatively

low density of Gilsonite). Each system usually is equipped with three centrifugal fans, each powered by a 75-kW electric motor. The Sprout Waldron centrifugal fans are arranged in series and together develop a vacuum of 140 in. of water gauge. The fans are connected to a 30-cm-diameter, steel airlift pipe, which is connected to a baghouse and bin arrangement. The airlift pipe extends from the baghouse into the mine. The capacity of the airlift system partially controls depth of workings and distance between shafts. The airlift system can efficiently transport Gilsonite in 335-m-deep shafts with 213-m-long drifts, but performance decreases if these distances are exceeded. The airlift system performs three additional functions: (1) it ventilates the mine; (2) it breaks the ore into smaller fragments (Gilsonite fractures easily during mining and transport); and (3) it removes the small amount of water that percolates into the mine. Occasionally, large inflows of water require pumping by 37-kW, staged pumps. Although the airlift system is expensive to operate, it is a versatile and proven technology.

Additional mechanization of Gilsonite mining has been limited by the following:

- Lack of equipment designed to operate in narrow veins
- The highly explosive nature of Gilsonite dust that complicates use of explosives and diesel-, gas-, and electric-powered equipment
- The need to prevent contamination by wall rock fragments, which favors careful hand mining of the ore

Despite these constraints, AGC experimented with several mechanical mining systems. During the 1950s and 1960s, AGC tried two methods of hydraulic mining and the use of a tunnel-boring machine (Kilborn 1964; Dewey 1965). Pneumatically powered "jet-cutting cars" mined horizontal benches underground using 13,800-kPa water jets to fracture the ore, which was then pumped from a sump to the surface. AGC later tried vertical hydraulic mining. Pilot holes were drilled vertically through the vein to intersect a drift at depth. A water-jet cutting bit was attached to the end of the drill string in the mine drift and the drill rig then reamed upward along the pilot hole, breaking the Gilsonite, which then fell to the drift below (Kilborn 1964; Dewey 1965). Neither hydraulic method has been used recently, in part because AGC no longer transports ore via a slurry pipeline. Drying the wet ore at the processing plant obviously is costly. AGC also experimented briefly with a tunnel-boring machine that drilled a 340-m-long tunnel in the Cowboy vein. It could mine Gilsonite at about 4.6 m/hr.

In September 2003, AGC contracted with a machine manufacturing company in Mt. Storm, West Virginia, to build a continuous mining machine. The unit is powered by a hydraulic power pack at the surface. A pressure hose and a return hose are threaded down the shaft and through the drift to the machine's location. The machine has a cone-type cutting head fitted with carbide-tipped bits and generally rides over the top of the 30-cm airlift pipe. Controls are similar to those of a normal backhoe. The unit is trammed forward or backward by activating hydraulic motors attached to steel tracks. A cutting drum is attached to a boom, which has horizontal and vertical movement along with boom extension. The cutting drum also is fitted with an additional hydraulic ram that allows the drum to move vertically. The machine was delivered in February 2004 and was immediately installed in the Eureka vein on drift development. This piece of equipment has doubled productivity.

PROCESSING AND PACKAGING

AGC hauls mined ore to a processing facility in Bonanza, Utah. The plant was rebuilt in 1981, effectively expanding its capacity to 109,000 Mtpy (Lewis 1994); the basic design, however, has not changed. Ziegler processes ore at its plant in Little Bonanza,

Utah, and Lexco processes Gilsonite at its plant southeast of Fort Duchesne, Utah.

Gilsonite from the AGC mines is hauled to the plant by 15-t dump trucks and is discharged into specific bunkers for each mine. Front-end loaders move the material from these bunkers into one of three bins. A drag conveyor moves the Gilsonite from the bottom of the bins onto a 1/4-in. screen where rock and mine debris is removed. Gilsonite is very friable, and 99% of the ore is broken to 1/4 in. by mining and transport. A drag conveyor moves the Gilsonite from the screen to a fluid-bed dryer where the coarse fraction (+65 mesh) and fines (-65 mesh) are separated. The plant was designed with five 1,400-t concrete silos that hold specific products such as oil-field products and foundry-grade material. The fines and coarse fraction are delivered to specific silos by pneumatic conveyance and by drag conveyors, respectively. About 15% to 20% of the Gilsonite is pulverized for use by the oil-field, ink, and foundry industries.

Gilsonite is withdrawn from the bottoms of the silos and discharged into one of two packaging bins. These bins serve two 23-kg paper-sack packers, two bulk-bag packers, and the bulk ore bin. Products are packaged, palletized, and shipped or warehoused according to customer specifications. Currently (2004), about 15% of the Gilsonite is shipped in bulk and 85% is packaged. About half the packaged material is in 23-kg paper sacks and half is in 907-kg supersacks. A small amount is packaged in smaller bags. Quality assurance testing is performed at the Bonanza plant, and a certificate of analysis is included with all orders. AGC ships all the products produced at Bonanza by common truck carriers.

Additional processing at the Bonanza plant includes blending different grades of Gilsonite; adding surfactants and dispersants to some specialty products (such as Bore-Plate); and solvent extraction, filtering, refining, and flaking of a refined resin product (ER Resin) for the printing ink industry. Users can also process the Gilsonite during product manufacture (e.g., filtering out grit during the manufacture of ink).

MARKETING

Uses

Gilsonite has an extremely wide range of uses; these uses have changed over time with new technology and industrial needs. Kemmerer (1934), Carey and Roberts (1949), Davis (1951), Kretchman (1957), and Remington (1959) give good summaries of past Gilsonite uses, and current uses are discussed in the following subsections.

Oil Well Drilling Mud Additive

For many years, Gilsonite has been added to drilling fluids to stabilize boreholes through shaly stratigraphic intervals, preventing borehole enlargement. Gilsonite plugs microfractures, bedding plane voids, and pore spaces and forms a thin film on the borehole wall. Gilsonite is added at about 1 to 3 kg per barrel of drilling mud (Davis and Tooman 1989). Gilsonite also reduces drill string torque and drag, and thus reduces the likelihood of stuck drill strings (J & J Specialty Products Inc. 2003). Bore-Plate, a specialty product for this application, is a mixture of Gilsonite grades (75% to 85% of the formula), surfactants, and dispersants designed for use in water-based oil well drilling fluids (AGC 2004).

Oil Well Cementing

Gilsonite is added to oil well cement for use in primary cementing of lost-circulation zones in surface, intermediate, and production pipe. It also is used for secondary cementing such as squeezing, recementing above inadequate fill-up, and plugging back to reestablish drilling fluid circulation (Slagle and Carter 1959). Gilsonite is used because of its low density, low water absorption, chemical inertness,

mechanical strength, granular nature, and minor deformation under high pressure. These properties allow Gilsonite to effectively enter, bridge, and seal lost-circulation zones. Typically 11 to 23 kg of Gilsonite is used per sack of cement (AGC 2004).

Asphalt Pavement Binder Modifier

Powdered Gilsonite is added to asphalt paving mixes to improve pavement performance. Gilsonite (1) increases stiffness and viscosity of the binder; (2) improves load-bearing capacity and reduces highway rutting; (3) improves ductility and resistance to low-temperature cracking; (4) increases durability of the pavement; and (5) improves workability of the mixture during paving. Typically 5% to 15 % Gilsonite is added to the mixture's binder (Asphalt Associates Limited 2003).

Asphalt Driveway Coater/Sealer

Asphalt preparations of Gilsonite, solvents, and other additives are used to coat weathered asphalt driveways, playgrounds, and other asphalt surfaces to improve appearance, reduce water infiltration, and slow deterioration of the asphalt pavement (Tamko Roofing Products 2003).

Built-up Roofing Component

Gilsonite is added to roofing asphalts. The compound acts as a waterproofing agent and as an adhesive that binds layers of roofing felt together.

Foundry Sand Additive

Gilsonite is an additive in sand mixtures used to make molds for casting gray iron and pig iron. Adding Gilsonite makes a better mold that imparts a smoother finish to the cast piece and is easier to remove from the cast item (AGC 2004).

Paint Component

Gilsonite is added to bitumen-based paints to increase hardness, adhesion, UV stability, and water and chemical resistance. Gilsonite paint formulations are often used on automobile frames and radiators. Gilsonite is also an ingredient in wood stains (AGC 2004).

Ink Component

Gilsonite and Gilsonite resin, derived by solvent extraction of raw Gilsonite, are used as carbon black wetting agents for black news ink and heatset and gravure ink. In addition to wetting and dispersing the carbon black pigment, Gilsonite or Gilsonite resin binds the pigment to the paper, yielding high-gloss print that resists rubbing off. Gilsonite can be mixed with other natural and synthetic oils, resins, and other additives to yield ink suitable for different types of printing presses and printing applications. Gilsonite typically comprises 2% to 5% of ink formulations. Refined Gilsonite resin is used in offset printing ink in concentrations of 15% or more to replace more expensive resins (AGC 2004).

Miscellaneous Applications

Gilsonite is used as an organic fuel in fireworks; for manufacture of high-purity carbon electrodes in the nuclear industry; as a binder in metallurgical additives and refractories; and in manufacture of contact and hot-melt adhesives, friction products, and pipe coatings (AGC 2004).

Geographic Distribution of Users

Locations of sales agents and distributors for AGC and Ziegler Gilsonite illustrate the global market distribution (AGC 2004; Ziegler 2004). Company-owned sales offices typically handle dis-

tribution in North America. The following list tabulates distributors by region:

	AGC	Ziegler
Asia/Middle East/Oceania	20	9
Europe	16	8
Central/South America	9	3
Africa	1	1

Product Pricing

The price of Gilsonite products depends on customer specifications, quantity ordered, type of packaging, sizing of material, chemical modifications of Gilsonite, industrial demand, competitor pricing, substitution of other materials in Gilsonite applications, and government regulatory mandates. Price ranges by application for 2004 were as follows (AGC 2004):

Industry Sector	Price Range, \$/Mt
Foundry molds	275–440
Oil well drilling and cementing	330–2,000 (Bore-Plate)
Asphalt and paving	500–660
Chemical products	550–1,000
Inks and paints	1,700 (ER Resin)

The most highly modified, value-added Gilsonite products are ER Resin and Bore-Plate. ER Resin is derived from raw Gilsonite by solvent extraction and refining, and sells for several times more than raw Gilsonite. Bore-Plate is a mixture of Gilsonite grades with added surfactants and dispersants designed for use in water-based oil-well drilling fluids to stabilize shale intervals in wells and to seal loss zones (AGC 2004). Bagging and pulverizing add about \$110/Mt and \$44/Mt, respectively, to each Gilsonite grade.

OPERATING COSTS

The costs to mine, process, package, and ship Gilsonite range from \$88 to \$770/Mt. These costs are directly related to mining conditions (vein width, ground control, royalty payments, and other factors); beneficiation requirements (adding special chemicals or other minerals to Gilsonite, sizing, blending, pulverization, and other requirements); and packaging requests (such as packaging into special types of bags).

LEASING, PERMITTING, AND RECLAMATION

Gilsonite producers rely on access to Gilsonite deposits on private, state, and federal lands. Before 1920, Gilsonite was considered a locatable mineral. Mining claims could be filed on federal lands (including lands that were surveyed and later transferred to the state), and patents were issued if mineral discovery requirements were met. For Gilsonite, these claims were issued for land 150 ft on either side of the vein and 1,500 ft long along the strike of the vein.

The Mineral Leasing Act of 1920 terminated the locatable mineral status of Gilsonite on federal land. Gilsonite on state lands has been by lease only since the land was surveyed and transferred to the state from the federal government. All leasing is done on a bid basis, and the successful bidder must pay annual production royalties of 10% of the sales price on both state and federal lands. Operators are allowed to deduct some beneficiation costs from the sales price to determine an adjusted sales price for calculation of the federal royalty. The federal government also charges an annual rental of \$1.24/ha. The Utah School and Institutional Trust Lands Administration (SITLA) manages the bulk of Utah state lands. SITLA charges a minimum annual rental of \$2.47/ha, but it can be higher and advanced minimum royalties can be imposed. All annual rentals and annual minimum advanced royalties can be

deducted from annual production royalties for the year in which they accrue. The leased lands are typically described by $\frac{1}{4}$, $\frac{1}{4}$ sections; in some cases, however, these 40-acre parcels are placed contiguously to describe larger lease areas. Those wishing to obtain a Gilsonite lease from SITLA must nominate the desired parcel for inclusion in SITLA's quarterly, competitive lease sale. Lessees are required to submit quarterly production reports.

The Utah Division of Oil, Gas and Mining (UDOGM) regulates exploration and mining on state, federal, and private lands. Exploration and mining plans must be approved by UDOGM and the federal or state agency that has jurisdiction over those lands. As of 2002, a UDOGM exploration permit requires a flat application fee and a reclamation bond based on the estimated number of acres disturbed during exploration. An annual exploration report is required at the end of the project or year's end, whichever comes first. Mine permit applications have two sets of rules based on estimated surface area to be disturbed; large mine permits govern disturbances of more than 5 acres and small mine permits govern disturbances of less than 5 acres. A small mine permit requires a flat application fee, a minimal permit application form, and a reclamation bond, but does not require a detailed reclamation plan. It also requires an annual report and an annual fee that is paid on a fiscal-year basis. A large mine permit requires a flat application fee, a more extensive mine permit application that includes a mine plan, and a detailed reclamation plan and bond. It also requires an annual report and an annual fee paid by fiscal year.

The U.S. Bureau of Land Management (BLM) manages exploration, leasing, and mine permitting on federal leases. There are two ways to initiate a lease through BLM:

1. In known Gilsonite resource areas, an applicant can obtain an exploration license. This requires (1) an exploration plan, (2) a fee, (3) a published invitation to others to participate in the exploration (applicants negotiate their own financial arrangements), and (4) a report at the end of the exploration. Applicants may then request that the land be competitively leased. On known Gilsonite resource areas, applicants also may request that the BLM competitively lease the land without first having an exploration license.
2. On land with no known Gilsonite resource, an applicant can request a prospecting permit; if valuable minerals are found, the applicant can apply for a preference rights lease that is good for 2 years. A report is required at the end of prospecting.

Once the applicant obtains a lease, several conditions must be met. The applicant must (1) file a mining and reclamation plan, (2) post a reclamation bond, (3) pay production royalties of 10% less some deductions, and (4) submit a quarterly production report listing ore mined and ore sold. Any exploration, construction, or mining requires an "impact assessment" to meet the requirements of the National Environmental Policy Act. The Antiquities Act, the Endangered Species Act, and other environmental impacts are addressed in the impact assessment. AGC, for example, uses 1.5 to 2 years as a rule of thumb for the time required to permit a mine.

HEALTH AND SAFETY

Gilsonite, as a finely powdered dust, is flammable and explosive but has no other serious safety, health, or environmental issues. There have been several serious mine explosions, and mine and plant fires in the 116-year history of the industry. Most accidents occurred long ago and in most cases probably involved obvious human error such as the use of open flames underground or improper blasting procedures. The last serious fire was in 1994 at Ziegler's Little Bonanza plant when plant maintenance sparked a

surface fire that injured two workers, destroyed some facilities, and burned 1,800 Mt of mined Gilsonite (Gomez 1994).

Gilsonite is nontoxic, noncarcinogenic, and nonmutagenic as classified in the U.S. Occupational Safety and Health Administration's material safety data sheets and the U.S. Food and Drug Administration Section 175.300, part 3, subpart (iv) (Ziegler 2004). FDA permits Gilsonite to be used in coatings that come in contact with food. Gilsonite dust presents no special respiratory hazards in mining or processing, although producers recommend wearing a respirator in very heavy dust environments.

Glaucanite

John H. Dooley

Glaucanite is a group of dioctahedral, potassium, iron-rich, compositionally heterogeneous, phyllosilicate (clay) minerals. In sufficient amounts, glaucanite imparts an olive green to greenish black color to sediment. Glaucanite-rich sediment is informally referred to as greensand, green earth, greensand marl, clay marl, sand marl, lime sand marl, or simply marl, as it is known in New Jersey. The term *greensand* as a rock name for glaucanite-bearing sediment is more appropriate than greensand marl or marl, terms that have been doggedly perpetuated in the literature. Marl, as currently used, is restricted to limey sediments, and therefore glaucanite sand in a limey, earthy sediment may be appropriately termed a greensand marl. Terms such as black marl, ash marl, poison marl, and acid marl have been used to describe greensands having strongly acidic properties (Tedrow 2002).

Because of its potash and phosphate content, greensand was mined and marketed as a natural fertilizer and soil conditioner for more than 100 years. The advent of manufactured fertilizers with adjustable nutrient ratios led to a decline in the use of greensand in agriculture. The material has since been recognized as useful in water treatment. Unfortunately, despite large reserves and worldwide distribution, glaucanite has not been used to any significant commercial extent because no major application has been found for a substance with its chemical composition and properties. This is due mostly to a paucity of research on its potential commercial uses.

Extraction of potash received considerable attention during and just after World War I. Because of relatively high extraction costs and a generally low potash content (less than 8%), glaucanite lost its appeal as a source of this commodity.

GEOLOGY

Glaucanitic greensands are unconsolidated sandy, silty, or clayey sediments of marine origin found in formations ranging in age from Precambrian to Recent (Figure 1). Although greensands are generally moderately sorted because of the presence of fine matrix, the glaucanite fraction of these sediments is usually well sorted because glaucanite pellets are remarkably uniform in size when autochthonous, although reworked (allochthonous) glaucanitic sediments can be poorly sorted (Amorosi 1997).

In the geologic strata, the contacts with overlying and underlying sediments are either gradational or unconformable. Primary sedimentary structures are generally lacking, but cross bedding, massive bedding, and bioturbation have been reported.

Figure 1. Comparative record of the relative abundance of glaucanitic peloids and chamositic ooids in the Phanerozoic

The clay (phyllosilicate) fraction in the greensand matrix consists of mainly illite/smectite, illite, micas, ferri illite, kaolinite, and chlorite (Bell and Goodell 1967; Seed 1968; Bremner and Willis 1993; Gibson, Bybell, and Mason 2000; Wiewióra et al. 2001).

Most greensand deposits contain, in addition to glaucanite, minerals such as quartz, mica, pyrite, some heavy minerals, and calcium carbonate in the form of shell or cement derived from marine organisms. Iron oxides, phosphatic nodules, fecal pellets, and foraminifera are locally common, and skeletal remains of marine vertebrates are occasionally found. Color photographs of glaucanitic cores from New Jersey are shown in Miller et al. (2004).

MINERALOGY

Glaucanite grains range from 1 mm (coarse sand) to the submicrometer (clay) and develop different shapes (Figures 2–5). The

Figure 2. Glauconite sand peloids (black) in a clay/silt carbonate matrix of the Navesink Formation from 1,013 ft depth in the Millville (New Jersey) corehole. An apatite (fecal?) pellet (P) is in the center of the photo. Note that in this particular core sample, the glauconite peloids are not in grain-to-grain contact but are supported by the clay/silt matrix. This is an example of a greensand marl. Scale on left side has 1-mm gradations.

Figure 4. Photomicrograph of glauconite sand peloids in the Upper Shark River Formation (New Jersey) from 631.6 ft depth in the Millville corehole. Morphologically, the peloids are smoother and less sutured (suturing obscured slightly) than those from the Navesink Formation (Figure 3). The Shark River glauconite may have been transported. The vermiform (banded) pellet in the center is likely glauconitized fecal matter (~47× magnification).

Figure 3. Photomicrograph of the typical morphology of glauconite sand peloids in the Navesink Formation from 1,013 ft depth in the Millville corehole. The peloids are highly sutured—typical of most evolved glauconite—with carbonate minerals filling the sutures (~35× magnification).

Figure 5. Photomicrograph of the cross section of polished glauconite sand peloids embedded in epoxy resin. Note the peloid to the right of center which has a void filled with a much lighter green mineral. Most peloids lack zonation (i.e. visually homogeneous from core to rim). Fractures, often infilled with minerals, are the characteristic sutures of mature glauconite.

largest percentage by weight is 0.49 to 0.125 mm (medium to fine sand). Grains are usually sutured or smooth and peloidal. Glauconite occasionally fills the interstices of coarse-grained sediments. Authigenic glauconite may form the cement or matrix.

Glauconite is a group of hydrous, iron, potassium phyllosilicates with a compositional range between glauconitic smectite and glauconitic mica (glauconite *sensu stricto*) end members (Odin and Matter 1981). Because of this range in end-member composition, glauconite has varying concentrations of the major constituent elements—aluminum, calcium, magnesium, and sodium—and many trace elements, for example, arsenic, lead, nickel, uranium, vanadium, and zinc. Its empirical chemical formula is

Table 1 shows the chemical composition of glauconite from New Jersey.

The chemical composition of glauconite was investigated by Foster (1969), who computed atomic ratios and layer charges for 32 samples from 12 countries. Table 2 shows the compositional range of these glauconites. Table 3 lists greensand analyses from 10 localities in the United States.

In the structure of mica, two silica tetrahedral sheets face one central octahedral sheet (Grim 1968). The tips of the tetrahedra

point toward the central unit, and the three sheets are combined into a single layer, with a suitable replacement of OH and O. As much as 25% of the silicon may be replaced by aluminum, and the resulting charge deficiency is balanced by interlayer potassium ions. In glauconite, aluminum can substitute for 4.2% to 17.5% of the silicon in tetrahedral sheets. Some of the charge deficiency is balanced by Fe⁺² and Mg⁺² ions replacing Fe⁺³ and Al⁺³ ions in the octahedral sheet. Most glauconite is not a pure dioctahedral phyllosilicate but rather a mixture of 10Å and 14Å expandable-lattice phyllosilicates (Burst 1958; Cimbalnikova 1971).

Like other layer silicates, glauconite absorbs ions from solution. Its exchangeable sites are on the outside of the silica-aluminum lattice, and the exchange reaction generally does not affect the glauconite structure. Both cations and anions are exchangeable, but not much information is available on the latter. Ion exchange is important in chemical separations, water softening, and the properties of soil for both agriculture and engineering. It is usually expressed in milliequivalents (meq) per 100 g, and a typical cation-exchange capacity (CEC) for glauconite is 20 meq/100 g.

The ternary plot by Yoder and Eugster (1955) shown as Figure 6 illustrates the compositional relationship between glauconite and other phyllosilicate minerals. Synonym (s) and varietal (v) terms for merly or erroneously used for glauconite include chloro-

rophanerite, mang anglaconite (v), marsjatskite, marsyatskite (manganoglaconite), sk olite (s), and soda glauconite (v) (Rieder et al. 1998). Pholidoide is a term used in Turkey for a group of aluminous glauconite.

MODE OF OCCURRENCE AND ORIGIN

Glauconite is found in rocks ranging in age from Precambrian to Recent (Figure 1); however, when the term *glauconite greensand* or greensand is used, a Tertiary or Cretaceous age is generally implied. The term greensand denotes an unconsolidated glauconite-rich sand. Glauconite frequently forms the major constituent in many sandy, silty, or even clayey formations of Tertiary and Cretaceous age. Greensand can be present as a solid massive bed, as disseminated grains, as glauconite-rich masses and aggregates, or as fillings in fossil worm tubes or foraminifera. Brown to grayish, ovoid, phosphatic (carbonate fluorapatite—francolite) fecal pellets can be accessory grains in greensand deposits (Figure 2). Fresh glauconite is typically olive green to dark green and has a polylobate to round or tabular shape.

The genesis of glauconite has been debated for decades. Three hypotheses have been proposed to explain its formation. The layer-lattice hypothesis (Burst 1958; Hower 1961) invokes the transformation under reducing conditions of degraded, detrital micaceous

minerals into a neoformed iron- and potassium-rich illite-group mineral. This process supposes a substitution of iron for aluminum in the octahedral sites, its balancing of the concomitant charge increase by potassium incorporation in the interlayer, thereby resulting in the synchronous fixation of iron and potassium within the lattice. Odin and Matter (1981) argue that the layer-lattice hypothesis is incompatible with several observations attendant with glauconitization.

The epigenetic substitution hypothesis (Ehlmann, Hulings, and Glover 1963) proposes that glauconite layers develop through solution of preexisting minerals with seawater furnishing the requisite ions.

The precipitation-dissolution-recrystallization (pdr) hypothesis (Odin and Matter 1981; Ireland, Curtis and Whiteman 1983) proposes that glauconite minerals result from neoformation of dissolved matter precipitated in pores in a progressively altered and replaced substrate. A precipitate forms as crystallites of green and (potassium-poor) glauconitic smectite, or as a silicic ferruginous gel, which transforms diagenetically to a glauconitic smectite in a slightly reducing microenvironment. The glauconitic smectite presumably ages to a better-ordered micaceous mineral (glauconite) as potassium is supplied from seawater at the sediment-seawater interface (known as the benthic boundary layer). Though the epigenetic substitution hypothesis supposes neoformation processes similar to those implied by the pdr hypothesis, the latter implies independence between the nature of the substrate and the neoformed iron-rich phyllosilicate.

A detailed Mössbauer investigation yields insight into one of several possible processes of glauconite formation (McConchie et al. 1979). Apparently, authigenesis starts with the defective or degraded phyllosilicate structure of an authigenic or detrital mineral decomposed in part by marine biogenic activity. The structure is highly charged but is temporarily neutralized by potassium, sodium, calcium, and particularly magnesium cations. Iron enters the structure as ferrous iron, replacing neutralized cations, and is partially oxidized to octahedral ferric iron. Ferrous iron continues entering the structure while the system proceeds toward equilibrium.

Based on principally strontium isotopic data for some glauconitic pellets, Stille and Clauer (1994) presented a two-stage evolutionary model for glauconite. The initial stage involves the dissolution of clay precursors and simultaneous crystallization in equilibrium with the precursor-dominated chemical environment until 4.5 wt % K_2O is achieved. The second stage consists of crystal maturation with increased potassium contents in equilibrium with the marine depositional environment.

Laboratory synthesis of glauconitic minerals under essentially "natural" conditions (Harder 1980, p. 221) demonstrates that "glauconite may form by the precipitation of iron hydroxides and adsorption of silica and K from dilute solutions...." He concludes that iron and aluminum in detrital minerals dissolve in reducing microenvironments and precipitate in more oxidizing ones in a variety of sediment substrates.

Scientific evidence for glauconitization favors dissolution-recrystallization processes rather than a progressive transformation of 2:1 phyllosilicates (Odin and Matter 1981; Stille and Clauer 1994). Despite the evidence, the transformation of detrital phyllosilicates could apply to specific cases of glauconitization. Research continues to focus on whether these hypotheses can adequately explain the formation of glauconite in a marine environment and the accumulation of greensand strata of considerable thickness and extent.

Glauconite forms widely in surface sediments deposited on continental shelves and topographic highs of all oceans except in

Figure 6. The relationships of dioctahedral phyllosilicate minerals, with fields indicated in which natural clay mineral compositions lie

extremely cold regions. It commonly forms in water depths of 50 to 500 m, with the highest abundance developing between 150 and 300 m, that is, at the shelf-slope transition. Glauconite authigenesis occurs at the sediment-seawater interface in areas characterized by low to negative sedimentation rates. Most glauconite deposits are associated with hiatuses and are used as a diagnostic feature of transgressive cycles in sequence stratigraphy.

Most glauconite peloids are cryptocrystalline in thin section, and their texture changes with progressive glauconitization. Texturally, authigenic glauconite peloids in their initial stage of formation often consist of tiny, ill-defined globules with diameters less than 0.5 μm . These coalesce, forming 2- to 3- μm rod-like or "caterpillar" crystallites. As authigenesis proceeds, 4- to 5- μm bladed aggregates form rosettes. Most evolved glauconite peloids consist of well-developed, slightly sinuous, subparallel, lamellae structures.

DISTRIBUTION OF MAJOR DEPOSITS

United States

The most important greensands are developed in the Mid-Atlantic Coastal Plain. Glauconite is found as an accessory mineral in many coastal plain sediments of New Jersey, Delaware, and Maryland, but highly glauconitic greensand is best developed in Upper Cretaceous and Early Paleocene formations.

Greensand crops out in a narrow belt that trends northeast-southwest across New Jersey, Delaware, Maryland, and beyond, but in general the glauconite content and thickness of the strata and the potash content of glauconite in them decrease southward. Table 1 shows the comprehensive chemistry of glauconite from New Jersey.

The Marshalltown Formation of Late Cretaceous age is composed of dark greenish gray, fine- to medium-grained, massive, highly glauconitic sand and silty fine quartz sand. Its thickness ranges from 3 m to more than 10 m.

The Hornerstown Formation of Early Paleocene age is a dark gray to dusky green, fine- to medium-grained glauconitic sand locally containing bright-green clay matrix and a little quartz sand.

Locally it contains a few thin, brown to reddish brown, clayey or indurated goethitic bands. Its thickness ranges from 1.5 to 7 m.

The Na vesink Formation of Late Cretaceous age is a dark greenish gray, medium-grained, massive, extensively bioturbated, poorly sorted, glauconitic sand containing varying amounts of quartz. It contains calcareous clay (marl) toward the top and goethitic bands or masses locally. Its thickness ranges from 3 to 7.5 m.

The Aquia Formation is composed of fine- to medium-grained, highly glauconitic sand with calcite-cemented layers. Its maximum thickness exceeds 35 m.

Other Countries

Glauconitic greensands are developed on all continents and have been geologically mapped in many countries. At some locations, glauconite is the most abundant constituent of the formation. In most cases, however, it is present in relatively small amounts or as a minor component of the sediment.

Australia

North of Perth in Western Australia, three glauconitic formations have a cumulative thickness of 90 m—the Molecap Greensand at the base, the Gingin Chalk, and the Poison Hill Greensand at the top. In some beds, the glauconite content reaches 50% of the sediment (McLeod 1965). The entire sequence is Late Cretaceous age (Brown, Campbell, and Crook 1968).

The Paleoproterozoic (c. 1800 Ma) Earaheedy Basin in Western Australia contains widespread glauconite in clastic units of the Chiall and Wongawall formations of the Minningarra Subgroup (Pirajno and Adamides 2000). Glauconite-rich strata of the Chiall Formation are interbedded with stratiform iron-manganese oxides, typical of passive continental shelf environments.

Brazil

The upper rhythmite of the Proterozoic Paranoá Group in the region of Cabeceiras in Brazil contains three glauconitic sandstones. Glauconite concentration ranges from less than 10% in the white sandstone to more than 50% in the green-reddish sandstone (Guimaraes et al. 2000).

Egypt

In the Western Desert of Egypt, the upper part of the Nubian Sandstone is composed of a 380-m-thick sequence of gray-green, very glauconitic shale, alternating with sandstone. It is Early Cretaceous age (Said 1962).

England

The Upper Greensand Formation is composed of highly glauconitic siltstones and sandstones and is developed in the southern and southeastern parts of England. The formation is well exposed at Ballard Cliff (Bennison and Wright 1969).

Hungary

The Lower Cretaceous age Nana Formation in the Transdanubian region is composed of highly glauconitic marls. The largest concentration of glauconite is in the lower part of the formation.

In the southern part of the Buda Mountains, clays and sands rich in glauconite are well developed in the Torokbalint Formation of Oligocene age.

Israel

The Cretaceous-age glauconitic sediments in the Negev Area of Israel first appear in the Hatira Formation and continue for several

meters into the overlying Hazera Formation. In some beds, glauconite makes up 80% of the rock (Bentor 1966).

The Pliocene-age Abu Hareira Sandstone is a hard, cross-bedded, glauconite-rich sandstone. The formation is best developed between Gaza and Beersheba (Picard and Solomonica 1936), with a maximum thickness of 30 m.

Lithuania

According to Smith et al. (1996, p. 2883), in their evaluation of the sorption of heavy metals by Lithuanian glauconite, "Several hundred million metric tonnes [are] reportedly accessible (i.e., at or near the surface) in Lithuania."

New Zealand

All major glauconitic deposits in New Zealand are found on South Island.

The Iron Creek Greensand is a highly glauconitic, massive sand in the Iron Creek Area. The formation reaches as much as 250 m in thickness and is of Late Cretaceous to Eocene age (Gage 1970).

The Waipara Greensand, which is of Paleocene–Eocene age, consists of alternating soft and hard, green, richly glauconitic sandstones. It is exposed in banks of the Waipara River and the south branch of the Waipara River.

The Kokoamu Greensand is pure, highly glauconitic sand. The formation is of Late Oligocene age and is developed and exposed in the Duntroon Area.

The Gee Green sand is exposed in the coastal Kakanui Area. The formation shows distinct stratification and is very glauconite rich. It is at least 15 m thick and is of Oligocene–Early Miocene age (Gage 1957).

Pakistan

The lower member of the Chichali Formation in Pakistan in the western Salt Ranges, Trans-Indus Ranges, and parts of Kohat is composed of sandy glauconitic shale that passes upward into dark green glauconitic and fossiliferous sandstone (Danilchik and Shah 1967).

South Africa

One of the most extensive glauconite (and phosphorite) deposits in the world mantles the southern African west coast and the Agulhas Bank continental shelf sediments (Coles et al. 2002). The major part of the Igoda Formation, which is of Late Cretaceous age, is composed of highly glauconitic sandy limestone and glauconitic calcareous sandstones. The formation is exposed in cliffs on the southwestern side of the Igoda River (Klinger and Lock 1978).

Switzerland

The Altmann Schist of Early Cretaceous age contains highly glauconitic layers, reaches a maximum thickness of 40 m, and is best developed in the Helvetic Alps, especially near Santis and Pilatus in Switzerland (Funk 1971).

Thailand

The green sandstones of the Phra Vihan Formation of Thailand are rich in glauconite. The formation is of Early Jurassic age and is well developed on the Khorat Plateau (Ward and Bunnag 1964).

Former U.S.S.R.

Glauconitic sandstone is widespread in the northwestern region of the European former U.S.S.R. It occurs in Ukraine, in the Volga

region, on the eastern slope of the Ural Mountains, in Kazakhstan and in Uzbekistan, and also in the Far East. These glauconitic deposits are mainly in Jurassic, Cretaceous, and Paleocene sands and sandstones. Their glauconite content commonly reaches 50% to 80%.

Venezuela

The Cogollo Group in Venezuela includes a sequence of sediments containing as much as 80% glauconite. The group reaches 610 m in thickness, is of Early–Late Cretaceous age, and is well developed in the central Lake Maracaibo Area (Bartok, Reijers, and Juhasz 1981).

West New Guinea (Irian Jaya)

The Kembelangan Formation, which is Jurassic to Paleocene in age, is well developed in the Vogelkop region of West New Guinea. Its Upper Cretaceous age portion is very glauconitic. Glauconite usually makes up more than 50% of the rock.

PROPERTIES

Magnetic Susceptibility

Glauconite has a variable paramagnetic susceptibility. Magnetic separation is, therefore, a commonly used method for separating it from impurities. With a Frantz Isodynamic magnetic separator, the following settings generally give a clean separation of glauconite from quartz, coprolites, pyrite, and calcite grains:

Side slope	20°
Forward slope	15°
Current	0.50 A (ampere)
Mass magnetic susceptibility	$(K_m) = 25 \pm 5 \times 10^{-6}$

Three steps of medium-intensity magnetic separation, preceded by washing and removal of +0.59- and -0.074-mm fractions, result in purified glauconite. The purified glauconite then can be effectively separated into differently evolved fractions by incrementally decreasing the current. This results from increasing magnetic susceptibility (and specific gravity) as glauconite evolves from glauconitic smectite to glauconitic mica.

Specific Gravity

The specific gravity of glauconites ranges widely depending on the abundance of mixed-layer minerals and K_2O , the degree of substitution in the tetrahedral and octahedral sites, and the extent of weathering. Shutov et al. (1972) reported the results of careful fractionation of purified glauconites by means of a density column, which permitted separation in heavy liquids in steps of $0.020 \pm 0.001 \text{ g/cm}^3$. The specific gravity of glauconite of various geologic ages and provenances ranged between 2.32 and 2.92. Odin and Matter (1981) report the specific gravity of glauconite to range between 2.2 and 2.9.

The wide range in specific gravity of glauconite limits the effectiveness of heavy liquid separation as a purification method. It can be used on some greensands with good results to separate mixtures of glauconite of different provenances and different stages of diagenesis.

Thermal Characteristics

Thermal curves for glauconites show weight losses between 80° and 255°C and between 520° and 825°C. The first temperature range corresponds to dehydration, the second to actual decomposition of the mineral (Smykatz-Kloss 1974). Prolonged heating at 1,000°C results in the formation of maghemite, which inverts into hematite (Spoljaric and Crawford 1980).

TECHNOLOGY

Exploration

Standard exploration procedures consist of outcrop examination, trenching, split-spoon and auger drilling, and sampling. Drilling is essential for determining the extent of a deposit and its thickness. Exploration data are used to construct geologic, isopach, isograde, and other maps; to calculate the volume of a deposit; and to determine minable reserves. Field examination commonly involves only the determination of color, grain-size range, and clay matrix content to make certain that the deposit meets required criteria.

Evaluation of Deposits

Whether a deposit of glauconitic greensand is suitable for commercial exploitation is determined largely by the physical and chemical properties of the glauconite itself. Both field and laboratory tests are employed in this determination. Important physical properties include color, grain size, degree of sorting, and the amount of glauconite in the unconsolidated or poorly indurated sediment. Economically acceptable greensands contain at least 90% sand-size glauconite. For use in filters, glauconite must be green, dark green to almost black, and must be present in sand-size pellets. Deposits should contain not more than 2% to 3% clay matrix and must show no evidence of weathering.

Chemical properties are determined by analytical means and include analyses for major elements (Si, Al, Fe, Mg, Ca, Na, K, and P) as well as some trace elements. Chemical composition is especially important for greensand used in agriculture. Most important are the K content, which should be at least 6% (as K_2O) and devoid of pyrite. Agricultural greensand deposits must be fine-grained, preferably clayey. Once a glauconitic greensand is determined to be of commercial quality, the reserves available in the deposit must satisfy the producer's production requirements.

Mining

Most Cretaceous and younger greensand deposits are unconsolidated sediments. Various methods of open-pit extraction have been used, ranging from pick and shovel in the earliest days to power shovels, draglines, and hydraulic mining. Inversand Company's operation at Sewell, New Jersey, which is currently the only commercial greensand producer in the United States, uses hydraulic mining methods in the Hornerstown and underlying Navesink formations. The pit has been opened to a depth greater than 15 m. Overburden, consisting of sandy units of the Kirkwood Formation, is about 7.5 m thick and is removed before greensand extraction. The lower part of the Hornerstown Formation, which constitutes the upper part of the deposit, is 5 to 6 m thick and overlies 3 to 4.5 m of nearly pure glauconite belonging to the Navesink Formation. After the beds are slurried by a jet of high-pressure water, the greensand is pumped from a sump through a pipeline to a tank at the nearby processing plant.

Agrolith A/S, a wholly owned subsidiary of Mineral Development International A/S (Birkeroed, Denmark), is the sole commercial producer of glauconite in Europe.

Processing and Purification

Processing at Sewell, New Jersey, involves first the screening of crude, mine-run greensand. Approximately two thirds of the crude is recovered as -1.0- to +0.25-mm feed for the production of manganese greensand. The remaining one third consists of -0.25- mm material that is too fine for use as a water filtration medium. The -0.25- to +0.088-mm fraction is stockpiled and sold as a soil conditioner and natural fertilizer, and the -0.088-mm fraction is pumped as waste to settling ponds. Agrolith A/S supplies glauconite with a

grain-size distribution having 98 % less than 0.25 mm and 10 % less than 0.10 mm (Coles et al. 2002).

After screening, the -1.0- to +0.25-mm fraction is washed for 2 hr with clean water to remove silt and clay. This is followed by several chemical treatments. Treatment with each chemical solution is followed by a fresh water rinse before the next chemical is used. The treatments each take between 0.5 and 1.75 hr. The first four treatments are with solutions of sodium aluminate, sodium silicate (twice), and aluminum sulfate. These chemicals harden the glauconite particles. The next eight treatments use manganese sulfate and potassium permanganate to build a manganese dioxide coating on the glauconite. This coating is the active agent in removal of iron, manganese, heavy metals, hydrogen sulfide, and radium from water.

The total time required for all chemical treatments is approximately 14 hr. Afterward, the material is slurry-pumped to a drying building, drained of most of its free water in holding pans, and dried in gas-fired ovens. The drying time for each batch is approximately 20 hr. The material is then packed in 0.03-m³ bags or 1-t supersacks and is palletized and stretch wrapped for shipment.

PRODUCTION

Historical Background

Greensand was used as a fertilizer in New Jersey in the latter part of the 1700s. During the early 1800s, its use became more common; applications of as much as 22.5 kg/m² were sometimes made, although recommendations for agricultural use suggested 4.5 to 11 kg/m² (Tedrow 1957). Many crops, especially the forage type, were said to improve with greensand application; because of its slow release of potash, however, large quantities were required. Certain greensands that contain sulfur and sulfide minerals are harmful to plant growth, and these were classified as poison, burning, or black marls. The availability of higher-grade potash salts from other mineral sources and the manufacture of prepared fertilizers displaced the agricultural use of greensand during the latter 1800s.

During the mid-1800s, the greensand industry, centered in a small section of the eastern United States, grossed more than \$500,000 per year. Toward the end of the century, however, annual

production dwindled to less than \$100,000. By 1910, only six or eight greensand producers were grossing less than \$5,000 per year each (Tyler 1934). The U.S. industry revived briefly during World War I because of the curtailment of foreign potash, especially from Germany.

During the latter 1940s and early 1950s, greensand was again recommended as a food nutrient for plants and farm crops. Agronomic studies discussed its potential as a soil additive that gradually releases potash and many trace element nutrients essential for plant growth (Tedrow 1957). Greensand was sold with the idea that it would condition soil and absorb and hold water while its base-exchange properties released trace elements.

For a short time, glauconite was used in certain parts of New Jersey as a binding additive in the brick industry. In the 1800s, it was used for making green glass (Cook 1868).

In the early 1900s, the base-exchange properties of glauconite were recognized for water treatment and the mineral gained acceptance as a water softener. Mansfield (1922) does not mention base exchange, even though this phenomenon was known in 1916 or earlier. From 1916 through 1922, several patents for the use of glauconite as a water-softening agent were granted. A method was also patented for treating greensand to improve it for water softening and ready regeneration with common sodium chloride brine (Borrowman 1920; Spencer 1924; Kriegsheim and Vaughan 1930).

Treated glauconite, on contact with water containing magnesium or lime, takes up magnesium or calcium ions and releases sodium ions. This exchange is limited to the outer surface of glauconite grains, and when all the surfaces have absorbed their capacity, the grains must be regenerated. Regeneration, simply stated, consists of treating or backwashing the glauconite with a sodium chloride solution, which replaces the hard-water elements with sodium, thus reviving the glauconite. The process has become more sophisticated because of competition among companies in the water-softening business.

Greensand products for water softening generally consisted of several different grades distinguished by the particular treatment the glauconite was given during processing. The standard greensand water softener was produced from natural glauconite that was only washed and classified. Table 4 gives its characteristics for water softening.

To increase its water-softening capacity, glauconite was treated by a process that made it more porous. Although most of the specifications remained the same as those for the washed greensand shown in Table 4, the porosity changed from 2%–3% to 11%–13%, and the exchange capacity (as CaCO₃) increased from 6.4–6.9 kg/m³ to 8.6–10.2 kg/m³. Maximum permissible raw water turbidity dropped from 10 ppm to 5–7 ppm, and the maximum permissible iron in raw water decreased from 2.5 to 1.5 ppm. By increasing the porosity of glauconite even more, the exchange capacity was also further increased, with a corresponding change in some of the other specifications. This special porosity process increased the salt requirement for regeneration, for example, from 22.4 kg/m³ to 40 kg/m³. Another method of processing greensand involved heating it to approximately 200° to 400°C to drive off water. After cooling, it was treated with salt brine, which made the greensand product more efficient because softened water did not become cloudy.

During the latter 1940s, greensand was displaced as a water-softening agent by phenol formaldehyde resin, which has twice the softening capacity, is not affected by water temperatures above 45°C, and requires the same amount of salt for regeneration. After 1950, phenol formaldehyde resin was displaced by styrene resins, which have an even higher water-softening capacity but require no more salt for regeneration.

In the late 1860s, almost a million tons of green sand were mined each year for use as fertilizer. In 1855, greensand brought \$0.07/bushel (\$2.00/m³), and in 1877 it was selling for \$0.65/t at the pit. Reports indicate that production was principally from New Jersey. By the 1870s, annual production had dropped to less than 100 ktpy. Toward the turn of the century, demand for greensand improved, but in 1908 fewer than 10,000 t were produced, for a total value of only \$3,500. The number of producers dropped from 13 in 1908 to 4 in 1912. The use of greensand for water softening in the early 1920s revived the industry. Table 5 shows the tonnage produced in New Jersey from 1922 through 1971.

In 1926, Inversand Co. started operations near Sewell in Gloucester County, New Jersey. In the late 1940s, National Soil Conservation Co. started operations at Medford in Burlington County, New Jersey, and produced greensand at that location until the early 1960s. Table 6 shows the production of New Jersey greensand for water treatment and agricultural uses from 1959 to 1963.

USES

Present-day use of glauconite is limited to two applications—water treatment and soil conditioning. Production is concentrated in the coastal plain of New Jersey, where greensand is extracted from Cretaceous and Paleocene age sediments. A small amount of greensand for soil conditioning was once mined in Maryland (closed in 1970) and Virginia, leaving New Jersey as the sole producer in the United States.

Inversand Co., a Division of Hungerford & Terry, Inc., produces processed greensand, also called manganese greensand, in the United States. In water treatment it is used as a filter medium for removing soluble iron or manganese salts and hydrogen sulfide from well water. It is employed in vertical and horizontal pressure filters and open-gravity filter systems by almost all water-conditioning equipment manufacturers. Purple to almost black manganese greensand is used in two water treatment processes. In the older, intermittent regeneration (IR) process, it is regenerated intermittently with a weak solution of potassium permanganate (KMnO₄).

A newer process, developed and patented by Hungerford & Terry around 1960, has replaced the older one and is called continuous regeneration (CR). Potassium permanganate is injected directly into the raw water upstream of the unit containing manganese greensand and may be preceded by chlorine injection. In this process the greensand does not require intermittent regeneration, only an occasional wash. The CR process uses potassium permanganate more efficiently than does the IR process and has gained favor because of its ability to reduce very high iron levels in water to extremely minute amounts, frequently to less than 10 ppb. When a well water supply contains very little iron but significant quantities of manganese, then the older IR process is more appropriately used.

For home and garden use, greensand is recommended as a mulch, top dressing, and conditioning additive to soil for gardens, potted plants, and vegetable starting plots. It slowly releases nutrients, loosens clayey soil, is nonburning, holds moisture, and gradually contributes potassium to plants to stimulate photosynthesis. The usual application is 0.05 to 0.49 kg/m², although larger amounts may be applied depending on the nature of the soil.

A number of other uses have been suggested or tried locally. Finely ground glauconite has been used as a green paint pigment, but its low refractive index and tendency to weather to red iron oxide inhibit its suitability for this application. This niche market has been resurrected, however, by the marketing of glauconite from the Baltic states as “natural earth pigments” to painters of Russian religious icons. For variations in color and texture of the pigment, greensands (not necessarily glauconite) used by icon painters were

mined from such diverse sources as celadonite from Monte Baldo near Verona, Italy, in 1574; chlorite from Cornwall in England; and greenish bentonite from northern Bohemia (Hradil et al. 2003). Greensands were mined also from the Baltic states, Cypress, France, Poland, Saxony, and Mendip Hills of England.

Pure glauconite has been used to a limited extent as a glass-polishing agent. Glauconite from the Weches Formation in Texas contains clayey beds that were formerly cut or sawed and dried to form a tough, reasonably durable building stone (Jones 1936; Fisher 1965).

FUTURE TRENDS

Potential New Uses

In light of declining demand for greensand, efforts have been made recently to develop new uses. Glauconite's catalytic properties have been investigated in some detail in the United States, the former U.S.S.R., Japan, Germany, and France (Hartough and Kosak 1947; Kvirikashvili 1962, 1964; Gornak 1963). Acylating reaction, dehydration of cyclohexane to benzene, condensation of aldehydes, and oxidation and dehydrogenation of alcohols have been carried out with glauconite-based catalysts. The relationship between catalytic activity and CEC has encouraged efforts to enhance the former by increasing the latter through heat treatment and chemical methods. Because CEC increases with the amount of mixed-layer component present, these efforts also have focused on replacing more of the potassium in the glauconite structure with hydroxyl ions. Heating of glauconite in a reducing atmosphere leads to the formation of metaglauconite, the sorptive properties of which are being studied.

An entirely different approach is the destructive dissolution of glauconite and recovery of at least three marketable products, high-purity silica, potash, and iron oxides. Turrentine (1925) first proposed this process. Efforts are under way to prove its economic feasibility with the help of modern chemical engineering practice.

Some extensive greensand deposits are situated near population centers, so glauconite's capacity to absorb hazardous waste fluids is being investigated. Recent studies in Germany and the

United States suggest that glauconite can be used as a filter for radioactive wastes (Kohler 1976) and heavy metals from landfill leachates and industrial effluents (Spoljaric and Crawford 1978, 1979). The efficacy of using manganese greensand to remove arsenic from water and hazardous waste liquids has been studied (Subramanian et al. 1997; Hanson et al. 1999). An increasing demand for this mineral in solving pressing pollution problems can therefore be anticipated. Food shortages in several parts of the world may also bring about renewed interest in glauconite as an inexpensive fertilizer and soil conditioner.

ECONOMIC FACTORS

Pricing

The list prices effective March 2004 for manganese greensand sold by Inversand Co. ranged from \$915 to \$990/m³, depending on the quantity purchased (R. Biegenwald, personal communication). All prices were free on board (f.o.b.) from the point of shipment in New Jersey. Agrolith A/S sold glauconite sand, consisting of about 95% glauconite, 2% quartz, and 3% "clay," for \$450/m³ ("300US\$ per tonne," according to Coles et al. 2002). Standard packaging consists of 0.028-m³ bags stretch-wrapped on pallets holding 25 bags each, an octagonal box strapped to a pallet and holding 0.71 m³ of product, or supersacks holding 1 t each.

Marketing and Distribution

The two avenues of distribution for manganese greensand are dealers and original equipment manufacturers. Dealers are primarily small- to medium-size water treatment companies that resell tanks, chemicals, and so forth, and provide service for domestic and other small water systems. Original equipment manufacturers design and manufacture equipment for large-scale municipal and industrial installations, and smaller commercial and domestic systems, and provide service for these water treatment facilities. They receive a small price incentive for making large single orders and promote the product. Many dealers are located in the midwestern United States. Large dealers in Europe distribute greensand from ports of entry in Sweden and Italy. Inversand Co. has also shipped greensand to Indonesia, South Korea, Trinidad, Chile, and Thailand in past years. A large manganese greensand water treatment system, possibly the largest ever, was built in Saudi Arabia in the late 1980s.

Alternate Materials

Low pH commonly causes unacceptably high concentrations of dissolved iron in water. This problem can be corrected with a neutralizing calcite filter, a water softener, raising the pH to a minimum of 6.7, or oxidation with chlorine bleach followed by filtration. Manganese can be removed from water by reverse osmosis and by oxidation with chlorine bleach followed by filtration. Small concentrations of manganese can be removed with a water softener. Hydrogen sulfide in concentrations greater than 6 ppm is treated with constant chlorination followed by filtration/dechlorination (McGowan 1984; Anon. 1978).

GOVERNMENTAL FACTORS

Zoning and Land Use

The area of southern New Jersey where glauconitic greensand is produced is heavily populated. It is likely, therefore, that any new mining permits or changes to present land use zoning to accommodate expansion of the greensand mine will be difficult to obtain. Inversand Co. reserves are proprietary data, although their reserves are sufficient to meet current or increased demand for many more years (R. Biegenwald, personal communication).

Environmental Regulation

Inversand Co. is required to comply with a number of environmental regulations and to operate a wastewater treatment plant under the jurisdiction of the New Jersey Department of Environmental Protection (New Jersey Pollutant Discharge Elimination System, or NJPDES). The company must have permits for both surface water discharge and groundwater discharge. Its operations are inspected periodically by the Mine Safety and Health Administration (MSHA), which checks workers for exposure to crystalline silica dust and enforces regulations regarding safety practices.

ACKNOWLEDGMENTS

The author thanks Bob Ganis, associate editor, for his comprehensive review of this chapter. The author is indebted to Frank J. Markewicz (retired) and William Loddin g (deceased) who wrote this chapter for the 4th edition of *Industrial Minerals and Rocks*, John Hower (deceased) who wrote the revised chapter for the 5th edition, and Nenad Spoljaric (retired) who updated this chapter for the 6th edition of *Industrial Minerals and Rocks*. Many parts from the 6th edition, some with only minor modifications, are included in the present edition.

Graphite

Harold A. Taylor Jr.

INTRODUCTION

This chapter will be restricted mostly to elemental carbon in the form of natural (mined) graphite. Elemental carbon also takes the form of diamonds and fullerenes, both with different crystal structures than graphite. Graphite also can be synthesized by bringing a carbonaceous material to the temperature of graphitization; most commonly, petroleum coke is used. Either graphite shapes (i.e., electrodes) or powder can be made in this manner. Synthetic (artificial) graphite powder and natural graphite are often substituted for each other, or mixtures containing both kinds are prepared for customers.

History

Prehistoric man used graphite to make drawings on cave walls and the Egyptians used it to decorate pottery. As early as 1400 AD, graphite crucibles were made in the Haffnerzell district of Bavaria.

Through the Middle Ages, graphite was confused with other minerals, especially galena and molybdenite. Two common names that are still used for the mineral are plumbago—meaning lead-silver—and black lead. The latter implies that graphite is either composed of lead or contains a large percentage of it. C. von Gessner is credited with having recognized it as a separate mineral in 1565, but its composition was not determined until 1779 when C. Scheele demonstrated that graphite oxidized to carbon dioxide, thus proving it to be a form of carbon. In 1789, A. Werner named it *graphite*, from the Greek word *graphein*, meaning “to write.”

The United States has long relied on imports for its graphite supply because of the lack of suitable domestic graphite reserves. Sri Lankan graphites were imported as early as 1820, and Madagascar graphites were imported following the opening of mines there about 100 years later. Mexico has long supplied the United States with most of its amorphous graphite requirements.

Classification and Industry Structure

Natural graphite can be divided into three classes: disseminated flake, crystalline vein (fibrous or columnar), and amorphous. Flake graphite is a lamellar form found in metamorphic rocks, such as marble, gneiss, and schist. Each flake is separate, having crystallized as such in the rock. Crystalline vein graphite (also called lump or high crystalline graphite) is found in well-defined veins or pocket accumulations along intrusive contacts of pegmatites with limestones. The graphite in these deposits is of two types, foliated and columnar. The Sri Lankan graphite deposits are vein type.

Amorphous graphite commonly is found as minute, microcrystalline particles fairly uniformly distributed in weakly metamorphosed rocks, such as slates, or in beds consisting almost entirely of graphite. The latter usually are metamorphosed coal seams with as much as 80% to 85% graphitic carbon, whereas the former are altered carbonaceous sediments, commonly ranging from 25% to 60% carbon. The graphite content of amorphous graphite deposits is dependent on the amount of carbon present in the original sediments; there is no evidence of enrichment by intrusive rocks. Certain amorphous graphite deposits undoubtedly were formed by contact (thermal) metamorphism, while others are probably the result of dynamic (regional) metamorphism.

Synthetic (artificial) graphite is manufactured in electric furnaces from petroleum coke.

Terms and Definitions

Graphite has been marketed as graphite, plumbago, or black lead. Industrial usage of such terms tends to be confusing to one not immersed in the industry. For example, the two main commercial categories of natural graphite are crystalline and amorphous; but all graphite is really crystalline and the commercial distinction is actually one of crystal size. Thus the term *amorphous*, although widely used, is a misnomer.

Amorphous can also refer to very fine particles of crystalline flake graphite that can only be sold for low-value uses, such as foundry facings. This very fine flake also is called crystalline dust. Fine-grained varieties of lump graphite easily reduced by grinding to fine particle size are called amorphous lump, distinguishing them from tough, platy, and acicular varieties (known as crystalline lump), which may be reduced in particle size only with difficulty.

Crystalline flake graphite is well defined in paragraph 213 of the Tariff Act of 1930 as follows:

The term “crystalline flake” means graphite or plumbago which occurs disseminated as a relatively thin flake throughout its containing rock, decomposed or not, and which may be or has been separated therefrom by ordinary crushing, pulverizing, screening, or mechanical concentration process, such flake being made up of a number of parallel laminae, which may be separated by mechanical means.

Under this definition, finely divided particles of crystalline flake graphite would be classified as crystalline graphite. But the

* Domestic production plus imports minus exports.

† All values in U.S. dollars.

‡ Preliminary.

§ Estimated.

U.S. Court of Customs and Patent Appeals has repeatedly held that commercial designations, not scientific terms, must govern classification and that when a commercial meaning differs from the technical meaning, the commercial designation has precedence. Thus, large quantities of fine-crystalline flake graphite are imported as amorphous graphite.

PRODUCTION, TRADE, AND RESOURCES

Salient Graphite Statistics

Table 1 shows the salient statistics for natural graphite in the United States and for total world production. There is no graphite mined in the United States. The statistics for apparent consumption is understated because the export numbers include natural-synthetic graphite mixtures. World graphite production statistics are usually preliminary for several years because many nations report figures very slowly; the statistics for some nations (e.g., India) are overstated because they are reported on an as-mined basis. The U.S. Geological Survey (USGS 2004) updates these statistics periodically and posts the data on its Web site (<http://minerals.usgs.gov/minerals>).

U.S. Graphite Consumption and Imports

There are almost no published statistics on U.S. consumption of natural graphite, by end use, because so much of USGS survey data are company proprietary. In addition, the numbers for amorphous graphite include natural-synthetic mixtures. In 2002, USGS data showed that 17,500 t crystalline graphite worth US\$16.8 million was consumed in the United States, compared to 15,000 t worth US\$15.8 million in 2001. In 2002, 21,900 t of amorphous graphite and mixes worth US\$18.4 million were consumed, compared to 18,800 t worth US\$14.7 million in 2001.

The U.S. import statistics shown by the USGS indicate that the major sources of graphite are China, which supplied 18,500 t worth \$6.55 million in 2002; followed by Mexico with 9,920 t worth US\$1.15 million; Canada with 8,360 t worth US\$4.31 million; Brazil with 4,190 t worth US\$3.67 million; and Madagascar with 2,030 t worth US\$0.97 million.

World Graphite Production and Resources

Table 2 shows that natural graphite is produced by 21 nations, led by China. China sets world prices, has a rapidly growing domestic market for graphite, and is a huge exporter. Brazil is a significant

exporter worldwide, and Mexico and Canada export mainly to the United States.

Table 3 shows graphite reserves and resources for a number of major graphite-producing nations.

GEOLOGY

Mineralogy, Crystallography, and Ore Impurities

Graphite is found in laminated, flaky aggregates disseminated in schistose rocks. It also occurs in veins and exhibits a foliated or fibrous structure. Graphite is a black lustrous mineral that crystallizes in the hexagonal system, with rhombohedral symmetry. The crystals are six-sided and tabular in form; the faces commonly are striated. The flakes have perfect basal cleavage and are opaque. When well-crystallized, flakes have a black metallic luster, whereas amorphous material is black and earthy with a microcrystalline compactness. The flakes feel greasy.

Physical and Chemical Properties

Graphite is an excellent conductor of heat and electricity. It melts at approximately 3,550°C at a triple point under 88 kg/cm². It sublimates between 3,300°C and 3,500°C at 1.033 kg/cm². At 3,726°C, a second triple point occurs at approximately 10,000 atmospheres. Thermal oxidation in the presence of oxygen begins at 300°C, and the rate increases with temperature. Graphite is used in lubricants and brake linings because of its lubricity (slipperiness) and in refractories because it is a good heat conductor while keeping its shape at high temperatures and does not react with molten metals.

The three forms of carbon (charcoal, graphite, and diamond) are distinguished by chemical and physical tests. The specific gravity of charcoal is 1.3 to 1.9; of graphite 2.266 g/cc (crystal density); and of diamond 3.5. Graphite has a hardness of 1 to 2 (Mohs scale).

Graphite has a meager chemistry and resists chemical attack by most reagents and is infusible in most common fluxes. It will form intercalation compounds with alkali metal vapors, mostly with potassium, rubidium, and cesium, where the metal ions fit between the planar carbon networks of the crystals, and the graphite structure is retained. Graphite will react with concentrated sulfuric acid to form graphite sulfate, but the reaction is easily reversed by merely adding water. Graphite oxide, a yellow substance known since 1859, is stable over a limited range around 200°C (392°F). It

converts into black pyrographitic acid below, or usually explodes above that temperature. Graphite fluoride is formed by exposing graphite to fluorine and hydrogen fluoride, and is of some interest as a high-temperature lubricant.

Origin and Mode of Geologic Occurrence

Graphite is widely distributed throughout the world, occurring in many types of igneous, sedimentary, and metamorphic rocks. Many occurrences, however, are of little economic importance. The more important occurrences are those found in metasomatic-hydrothermal deposits and in sedimentary rocks that have been subjected to regional or contact metamorphism.

Most, if not all, of the world's deposits of flake and crystalline graphite occur in metamorphic rocks of Precambrian age. Marble, gneiss, and schist are the most common types of rock in which economic deposits of flake graphite occur. In many cases, pegmatitic veins have intruded the rocks. Vein graphite is normally found in rocks similar to these, but the enclosing wall rock is not necessarily graphitic. This type of deposit assumes the character of a true lode.

Economic deposits of graphite include five main geological types:

1. Flake graphite disseminated in metamorphosed, silica-rich sedimentary rocks

2. Flake graphite disseminated in marble
3. Amorphous deposits formed by metamorphism of coal or carbon-rich sediments
4. Veins filling fractures, fissures, and cavities in country rock
5. Contact metasomatic or hydrothermal deposits in metamorphosed, calcareous, sedimentary rocks

Natural graphite in these deposits varies widely in physical appearance. Klar (1958) classified graphite occurrences on the basis of crystal characteristics into microcrystalline dense graphites and macrocrystalline silvery-bright graphites. Microcrystalline graphite occurs in deposits of high carbon content as exceptionally small crystals discernable only by high-powered microscopes, whereas the macrocrystalline type generally occurs in lower concentrations and in larger crystal form.

Each type is described in more detail in the sections that follow.

Flake Graphite Disseminated in Metamorphosed Silica-Rich Sedimentary Rocks

A large part of total world production of graphite is derived from rocks such as quartz-mica schist, feldspathic or micaceous quartzite, and gneiss. The graphite flakes in these rocks are oriented parallel to the plane of foliation. The graphite varies widely in physical appearance and characteristics. The flakes range in size from a fraction of

Table 3. World graphite resources (recoverable flake or crystalline concentrates or of amorphous graphite, kt)

† Known as high crystalline or lump, comprising crystalline lump and amorphous lump.

‡ Reserve base is Alabama only; inferred base is Alaska plus New York.

a millimeter to an average of 40 cm, and may vary by deposit in thickness, toughness, density, and shape.

The principal deposits of flake graphite are in lenses or layers as much as 33 m thick and some thousands of meters long. The lenses have variable graphite content, both within themselves and from one lens to another. The content of an average deposit is about 10%–12% carbon, but some deposits containing as little as 2% graphite have been mined. In Madagascar one rich lens contains 60% graphite. Crystals in each deposit vary in size, usually reflecting the grain size in the parent rock. In an above-average deposit, crystals as large as 4 cm across are common.

Deposits of this type of graphite are described by location in the sections that follow.

Alabama. The deposits of northeastern Alabama, in Chilton, Coosa, and Clay counties, occur in two northeast-trending belts, 1–3 km wide, with a combined length of about 90 km. Worked intermittently since the late 1800s, the mines reached their peak production during World War I. The deposits, called *leads*, are groups of parallel layers and lenses in the Ashland quartz-mica schist that contain 1%–5% disseminated flake graphite. The mined leads range from 6 m to more than 35 m in thickness, dip gently to

Table 4. Sample assay results

Size	Kilograms of Flake per Ton of Ore

steeply, and have been traced up to 1,200 m long strike. Some are essentially constant in strike and dip over long distances; others are folded, faulted, or both. The deposits are weathered to depths as great as 35 m. In general, the flake ranges from less than 1.25 mm to 5.00 mm in diameter, but most are less than 1.25 mm in diameter. Assays of samples from 32 properties in the northeastern belt by the U.S. Bureau of Mines gave the results shown in Table 4.

Most of the graphite produced in Alabama during and after World War II was formerly stockpiled, but Alabama graphite has been marketed for most common graphite uses.

Texas. The flake graphite deposits of Texas occur in the Precambrian Packsaddle Schist in Llano and Burnet counties. The deposits show a wide range of graphite content and flake size. The most important deposit was one in Burnet County, which was operated by the Southwestern Graphite Company.

Canada. The Lac Knife graphite deposit at Fermont, Quebec, has unusually rich ore; quite atypical of other commercially important Canadian deposits. The graphite deposit and its surrounding host rock, a quartz-feldspar (biotite) gneiss, usually migmatized, represent the southern extension of the Menihek shales and argillites of the Churchill Province into the Grenville Province. Garnet, kyanite, and pyrrhotite are associated minerals. The graphite is uniformly disseminated when the ore has less than 10% graphite. Graphite blebs appear in ever-increasing size as the ore increases in richness above 10%. When the ore is above 25% graphite, veins and massive zones of graphite are observed. The graphite occurs as independent grains, specifically medium to coarse flakes or masses of fine grains, or as inclusions in other minerals, including graphite interlain with mica.

Germany. Deposits east of Passau, Bavaria, near the Austrian border, were known to prehistoric man and have been worked since the Middle Ages. They consist of crystalline graphite in seams, lenses, and disseminated flakes in gneiss and schist. Individual seams and lenses up to 10 m in thickness are mined for a few hundred meters. At Kropfmühl, the only mine now operating, a very heavily folded bed of graphite is mined at eight successive depths in some places. This bed of graphite is interbedded with marble and micaceous gneiss in a zone that is 130 m in stratigraphic thickness. Exposures 0.5–1.0 m thick are mined. Graphite forms 10%–30% of the lenses. Associated minerals are mainly feldspar and calcite, and less quartz, pyrrhotite, pyrite, biotite, hornblende, sphalerite, and galena. Both weathered and unweathered rocks have been mined. Two grades of crucible flake (92%–97%), three of pencil flake (96%–97%), and five grades of fines are produced. The deposits are syngenetic and formed by metamorphism of organic carbonaceous sediments.

Madagascar. Probably the largest resources of high-grade, crystalline flake graphite in the world are on the island of Madagascar. The deposits occur in belts of micaceous gneiss and schist over a distance of more than 800 km in the eastern half of the island from the latitude of the city of Tamatave to the southern end of the island. The principal producing area extends about 110 km along the east coast from Tamatave to Marovintsy. Individual deposits are graphite-rich layers that range from 3.0 m to more than 35.0 m in thickness; some can be followed for a few thousand meters. The graphite content reportedly ranges up to 60%, but ore averaging 4%–11% disseminated graphite has been worked in recent years. Operations are confined to the weathered upper parts of the deposits, and reserves of weathered ore are considered ample for many years at current rates of production. Flake graphite from Madagascar is noted for its high proportion of coarse flake, uniform thickness, toughness, and cleanness, and for the care with which it is graded for export. It sets the world standard for high-quality flake.

Norway. In Europe the principal productive graphite deposits of Norway, Germany (Bavaria), and the Czech Republic consist of flake graphite disseminated in mica schist or mica gneiss or are closely associated with these rocks. The productive deposits of Norway (A/S Skaland Grafittverk) are on Senja Island in northern Norway (latitude, 60°39'N; longitude, 17°E), and are lenses of graphitic rock enclosed in mica schists. The richest ore contains 25%–30% graphite. The ore is hard and must be crushed to recover the graphite.

Flake Graphite Disseminated in Marble

Flake graphite disseminated in marble probably originated from carbonaceous impurities. Graphite commonly is less than 1% of the rock, although in some localities it is as much as 10%. Deposits of this type are structurally complex and exhibit much variation in grade and kinds of accessory minerals over short distances. Their contribution to world production is consequently much less than that from deposits in schists and gneisses.

The most significant graphite deposit of this type in the world is the Lac-des-Iles crystalline flake graphite deposit in Canada. The host rock is a jumble of Grenville biotite-garnet gneiss, quartzite, and graphite-containing marble. Although most of the graphite is found in the higher-grade marble core of a gneissic body, some larger-flake graphite is found in the quartzite ring surrounding the core. The entire sequence is cut by gabbro-diorite dikes and pegmatite bodies and is extensively folded and faulted.

Amorphous Deposits Formed by Metamorphism of Coal or Carbon-Rich Sediments

The graphite in deposits formed by the metamorphism of coal or carbon-rich sediments is almost invariably the microcrystalline variety known to the trade as amorphous graphite. A substantial part of world production of amorphous graphite is from such deposits. The graphite occurs in seams, often distorted by folding and faulting, and is commonly intimately mixed with nongraphitized material. The ratio of graphite to nongraphitized material can vary widely. For example, some high-grade Mexican varieties contain as much as 95% graphite, whereas low-grade Korean graphites are commonly burned for fuel because of high non-graphitic carbon content.

Deposits of this type of graphite are described by location in the sections that follow.

Austria. In southeastern Austria, large resources of graphite are present in a 50-km-long belt of folded metasediments extending from the towns of Leoben to Rottenmann in the Styrian Alps. There are two producing mines. At Kaisereberg, the principal mine, a series of graphitic beds with an aggregate thickness of 12 m are enclosed in graphitic schists and quartzites. Crude ore contains 30%–80% carbon and averages 50%–60%. Refined graphites ranging from 66%–95% carbon are produced by grinding and flotation. The products are amorphous graphite and are used for foundry facings, pencils, paint lacquer pigments, and lubricants.

Mexico. The most important deposits of amorphous graphite in the western hemisphere occur in the state of Sonora, Mexico, in an area 30 km long by 15 km wide, approximately 60 km southeast of Hermosillo. The deposits were discovered in 1867. Six beds of graphite are reported, the thickest averaging 3.0 m, but folding causes local swelling to 7.0 m. They were earlier described as beds of coal interlain with sandstone, folded, and then intruded by granite; the coal thereby converted to graphite. Recent detailed examinations, however, reveal the deposits at the Moradillas mine to be hydrothermal veins; no evidence has been found to indicate that they are metamorphosed coal beds. The veins are said to occupy fissures that cross the bedding of the country rocks at low angles. In the district as a whole, the graphite deposits are reported to be steeply dipping and are said to range from mere stringers to seams that are locally 4–5 m wide. High-grade Mexican graphite averages 80% carbon, but some contains as much as 95%.

The mineral suite for amorphous ore includes mica, clay minerals, tourmaline, and hematite with occasional pyrite and gypsum locally. The ore is prepared for shipment by hand-sorting out the

admixed rock from the hanging walls; then it is crushed, screened, and dried.

South Korea. The amorphous graphite deposits of South Korea, which have yielded about 2 Mt, occur as irregular lenses parallel to the structure of enclosing schists and as phyllites of sedimentary origin. In the Kyeong-Sang district, three seams having minable widths of 24, 6, and 15 m, respectively, have been reported. Deposits formed by dynamic and contact metamorphism of coal beds occur in southern Korea, but Overstreet (1947) reports that these are impure.

United States. In the United States, coals in the Narragansett Basin of Rhode Island have locally been metamorphosed to graphitic anthracite.

Veins Filling Fractures and Cavities

Veins of graphite are typically filled fractures or cavities in the country rock. In thinner veins, graphite occurs as crust or layers of closely packed, coarse, elongate plates (needle lump) oriented perpendicular to the vein walls. Plates vary in length with vein thickness and may be as long as 10 cm. Central portions of thicker veins may consist of platy layers with the crystals parallel to the vein walls.

The origin of graphite vein deposits is uncertain. Winchell (1916) discussed various hypotheses and concluded that the most probable mode of origin involved reduction of oxides of carbon.

The deposits of this type of graphite are described by location in the sections that follow.

Mexico. The most important deposits of amorphous graphite in the western hemisphere occur in the state of Sonora, Mexico, in an area south and east of Hermosillo and south and east of Navajoa. In addition to these strictly amorphous deposits, there are a few deposits such as the one at the Lourdes mine that have supplied vein graphite. Substantially more than half of the total state production formerly came from the Lourdes mine at Moradillas, now closed. These vein deposits, interlain with sandstone, consist of steeply dipping, north-south striking graphite veins ranging from small stringers to seams that average 3–4 m wide at depth. Some veins more than 6 m wide were mined. The graphite content averaged 85%–90%.

Sri Lanka. The graphite vein deposits of Sri Lanka have been worked systematically for more than 140 years, yielding more than 1.2 Mt of graphite since 1880. The main deposits are in Southern, Western, and Sabaragamuwa provinces. The deposits occur in a complex series of Archean granulites, quartzites, garnet-sillimanite gneisses, and marbles in narrow, structurally controlled belts that persist for many miles along the strike. The productive deposits range from simple fissure veins to branching veins or stockworks. Veins commonly are a few millimeters to almost a meter thick. Some of the larger deposits are tabular bodies parallel to the foliation of enclosing rocks. Graphite-filled vugs as long as 24 m and 2 m × 1 m in cross section are reported. The highest grades of Sri Lanka graphite carry 97%–98% carbon. A variety of minerals, chiefly quartz, pyrite, calcite, apatite, and pyroxene, and lesser rutile, allanite, magnetite, and various lime-magnesia silicates, have been reported to be associated with graphite in the veins, but it is not clear whether these minerals were deposited with the graphite or merely minerals of the wall rocks accidentally enclosed in the veins. Resources of graphite in Sri Lanka are probably very large.

United States. Deposits of this type at Sturbridge, Massachusetts, were mined in the 1640s, the first graphite mining in the United States. The only sizeable domestic vein deposits, however, are those at the Crystal Graphite mine near Dillon, Montana. There, graphite fills networks of fractures in gneiss and pegmatite around the northwesterly plunging nose of an isoclinal fold, a structure that

involves granite gneiss, schist, marble, and quartzite of the Precambrian Cherry Creek Series. The veins are a few millimeters to 60 cm thick and 1–15 m long. The formation of the veins has been related to the development of the pegmatites, but Ford (1954) later showed that fracturing and vein formation took place after the formation of these rocks.

India. Vein deposits have also been reported from southern India (e.g., in Tamil Nadu).

Contact Metasomatic or Hydrothermal Deposits in Marble

Concentrations of graphite occur in various parts of the world in silicified carbonate rocks. Some are clearly contact metasomatic; others show gradations to typical hydrothermal deposits. As a group, they are characterized by variability in deposit size (generally small), variability in flake size and content, and irregularity of form. The average grade of most deposits is low, and, consequently, they have accounted for only a minor part of total world production.

Distribution of Major Deposits

Africa. Zimbabwe's only producer is the Lynx mine near Karoi, although there are other deposits nearby. It is operated by its parent-owner, a subsidiary of Graphitwerk Kropfmühl A.G. of Germany. The ore is mined underground from a lenticular ore body running 20%–35% crystalline flake graphite. The ore is beneficiated by flotation to make products containing 80%–83% and 90%–94% graphite.

Graphites de Ancuabe Ltda. operated a sizeable mine and plant in Mozambique from 1994 to 1999, and Tanzanian graphite was mined near Merelani for a few years in the 1990s.

Australia and New Zealand. There are some medium-sized deposits in Australia. Several occurrences are also reported in New Zealand.

Austria. The graphite deposits in Styria are thought to have originated by the metamorphism of carboniferous and bituminous substances under high pressure and temperature, during deformation. The deposits, therefore, occur in comparatively small lenses and, with one exception, must be mined underground.

The major mines in Styria, some of the two centuries old, are near Kaiserberg and Triben. Geologically, these Alpine deposits are embedded in a zone of fine-grained, scaly schists in lenses and individual beds as much as 10 m thick. The ore is black, soft, fine-grained, and dense, with a carbon content of 40%–88%. It is low in sulfur (0.2%–0.3%) and iron and practically free of carbonate and phosphate.

The first and only flotation plant for amorphous graphite is at Kaiserberg. The process was developed in the laboratories of Franz Mayr-Melnhof & Company's subsidiary Grafitbergbau Kaisersberg, where fine (2 µm average particle size) graphite with 92% carbon is produced, suitable for lubrication, pencils, pigment, and drilling mud.

Brazil. The three major crystalline flake graphite mines are in the state of Minas Gerais, and belong to Nacional de Grafite Ltda. The mines are at Itapeceira, near Belo Horizonte, Pedra Azul, about 16 km from the Minas Gerais–Bahia boundary, and Salto da Divisa, 50 km from Pedra Azul. Pedra Azul is by far the largest producer of the three. The ores mined are graphite-containing soils, the results of very extensive weathering of the original host rock. Therefore, no blasting is required before the ore is removed by front-end loader or shovel. The ore at Itapeceira averages 20% graphite and occurs in numerous small pockets spread over an area of 130 sq km. Usually only a small number of these pockets are mined at one time. The ore at Pedra Azul averages 5%–12% graphite, is mined at a number of faces, and usually

blended to a mill feed running 6%–7% graphite. Beneficiation plants at the three locations use flotation to make a final product. A chemical leaching plant that produces high-purity (99.6%) graphite is located at Itapecerica.

A handful of very small mines located in the states of Minas Gerais and Bahia produce unbeneficiated product sold as is.

China. Graphite is produced in a number of provinces in China, of which two are by far the most significant. Shandong Province is a major flake graphite producer, and its major mines are the Nan Shu, Bai Shu, and Dong Guan. Bai Shu also has an exfoliated graphite plant. Heilongjiang Province is the other major producer, with three mines east of Harbin at Jixi: the Liumao (the largest flake producer), Lin, and Moshuan mines. Inner Mongolia produces graphite, mostly from the Xing Ho mine. Shanxi Province produces graphite from the Guodian and Deisheng mines. Hunan, at the Lutang mine, and Guandong provinces also produce graphite. China has very low production costs, which has allowed it to establish a major niche in the world market in the 1980s; however, domestic consumption of graphite has increased rapidly and infrastructure problems have appeared.

Commonwealth of Independent States and Ukraine. Graphite occurs in a number of places in the Urals, Siberia, Uzbekistan, and particularly the Ukraine. Reliable sources indicate that 75%–90% of the graphite produced is crystalline flake, almost all fine flake. Until the early 1980s this region was a significant exporter to most world markets, including the United States.

The biggest producer, probably accounting for 75% of total production or 60 kt, is the Zavalyevsky complex in the Ukraine, near Gayvorgan. The mine is an open-pit operation on steeply dipping ore bodies that range from 3 m to 35 m thick and produces ore grading from 3% to 7% crystalline flake graphite. The beneficiation plant also produces colloidal graphite products, lubricants, and high-purity graphite containing between 99% and 99.9% graphite.

Czech Republic. Graphite is mined in two areas, one in Bohemia near the Austrian border and one in Moravia near the Polish border. Both mine fine-grained crystalline flake or, more usually, crystalline dust from metamorphic host rocks, mostly gneiss or schist. In Bohemia, the ore contains 15% graphite; its beneficiation by flotation creates a product containing 80%–96% graphite, and a final leaching yields a 99.99% graphite product. In Moravia, the ore contains 30%–40% graphite.

Germany. The Passau district (Bavaria) has long produced flake graphite suitable for crucibles. Historical documents frequently refer to this graphite, which probably furnished the graphite in the Middle Ages for alchemists' crucibles. The graphite-bearing country rock is a part of the "kristallines Grundgebirge," the old gneissic and schistose rock of the Bohemian massif; the gneissic rocks are believed to have been metamorphosed during the Carboniferous period.

Today, Graphitwerk Kropfmühl A.G. produces flake graphite exceeding 96%–97% graphitic carbon suitable for crucibles, pencil leads, and lubricants. This company also chemically purifies graphite to +99.9% carbon in several size grades. The company mines one graphite bed (1.5 m thick) that is so tightly and heavily folded that it can be intersected eight different times in depth at many locations. Thicker layers occur in places because of folding. The ore runs 20%–25% graphitic carbon. It is beneficiated and processed by flotation, grinding, and screening.

India. The major graphite-producing Indian states are Orissa and Rajasthan, but Andhra Pradesh, Bihar, Gujarat, and Tamil Nadu also produce graphite. Orissa usually accounts for 65%–75% of all Indian production. Major companies include Agrawal Graphite

Industries, with mines near Ganjaudar and Temrimal in Orissa State, and TP Minerals Pvt. Ltd., with mines near Phulbani, Madagudarf, and Sargipali, all in Orissa State. Both companies produce a variety of crystalline flake and powder graphites, which mostly go to a wide variety of domestic end uses. The most important Indian end uses are in crucibles and foundries.

Indian graphite deposits usually occur in garnet-sillimanite-muscovite gneisses of the Khondalite group. Of the total reserves of recoverable graphite, 35% are located in Kerala State, 31% in Bihar State, 13% in Orissa State, and the balance elsewhere.

Madagascar. The African island of Madagascar is an important producer of graphite because of the size and quality of its flake. Occurrences are widespread along the eastern coast near Tamatave, in the central section near Tananarive, and in a southern section between Betroka and Bekily. Current production comes from the deposits along the eastern coast. The main producers are Societe Miniere de la Grande Ile and Establishments Galois. Each company markets its own graphite; graphites from different deposits are not blended.

The deposits are in a region where lateritic deposits of iron and bauxite also are found. The graphite occurs in highly metamorphosed schists and gneisses that have weathered deeply to soft, ferruginous clays. The graphitic content of the original rock has been raised through the natural leaching process. The graphite, being resistant to weathering, is found among the weathered residue.

The crude ore contains 3%–10% graphite, of which about two-thirds is large flake and one third is fine flake. Commercial interest is primarily in the large flake; it is strong, flexible, and is the best graphite for refractories. It is also favored for crucibles. The pyrometric cone equivalent of the ash is cone 16 to 20 and is higher than the ash of other flake graphites.

The nongraphitic portion of the flake product is uniform and consists (after oxidizing) chiefly of a clayey residue with some quartz and a sprinkle of accessory minerals such as mica, zircon, rutile, and epidote. Sulfur compounds are absent and iron is low.

Mexico. Sonora contains extensive deposits of amorphous graphite, and most Mexican graphite mines and mills are located here. The Sonoran deposits are homogeneous and contain about 80% graphitic carbon. They were discovered in 1867, and exploitation began in 1891. There are said to be as many as seven distinct beds of graphite within alternating layers of metamorphosed andalusite-bearing Triassic rocks.

The operating mines are located about 400 km southeast of the U.S. border in the region of Moradillas. This region is arid, and water for operation is scarce. Other amorphous graphite deposits are reported in the states of Baja California del Norte and Coahuila in northern Mexico, and Hidalgo and Guerrero in central Mexico.

Several crystalline flake deposits are known in Oaxaca; one of these has been worked at Teixtlahuaca. The owner, Grafito de Mexico SA de CV, beneficiated the ore nearby by flotation.

Norway. A/S Skaland Grafitverk has been the only operating graphite mine in Norway. Currently closed, it is expected to reopen. The deposit is on Senja Island in northern Norway. Flotation brings the carbon content up to 80%–93%.

Republic of Korea. The Republic of Korea is a minor producer of natural graphite and has produced both amorphous and flake products. The principal mining areas are in the provinces of Chung Nam, Kyong Gi, L yung Pak, and Kang Won, near Seoul. Almost all the deposits are in the vicinity of anthracite coal mines, lending support to the idea that the amorphous graphite is derived from coal.

Sri Lanka. Sri Lanka contains the largest known deposits of vein graphite. Very large deposits are located in the western and southwestern sections of the island. The extent of the deposits has inspired significant study, and although the resulting literature is extensive, little is known about the origin of the vein graphite. According to Wadia (1943)

The vein graphite deposits are believed (by some) to have been formed by reduction, at high temperatures and pressures, of carbon dioxide liberated during the assimilation of limestones and dolomites by charnockitic and related igneous magmas.

The structures of these ore bodies contrast markedly with those of other forms of graphite and are typical of vein, dike, pegmatitic, or pneumatolytic ore deposits.

Almost all high-quality vein graphite comes from Sri Lanka. Despite rising labor costs, most of the production is still done by hand cobbing and hand sorting to satisfy buyers who still retain a preference for lump grades. Because most graphites are used in industry as a powder, the current operators anticipate a trend toward supplying the powder directly from the mine to the importer, thus reducing hand sorting.

Sri Lankan graphite is highly graphitized; the best grades are completely graphitized. It is favored for lubrication, pencils, electromotive brushes, and other uses requiring high-quality graphite. A subsidiary of Kropfmuhl A.G., Bogala Graphite, is the producer.

Sweden. Woxna Graphite AB produced graphite briefly from a deposit near Edsbyn.

United States and Canada. Graphite is no longer produced in the United States. The lone flake producer, Southwestern Graphite Company in Burnet, Texas, closed its mine operation in 1980. The graphite plants in the United States process imported graphites that are beneficiated, ground, and blended as required to maintain individual company specifications.

Flake graphite deposits in both Alabama and Pennsylvania have been worked intermittently; the last Alabama mine closed in 1953 and the last Pennsylvania mine in 1961. Rhode Island stopped producing amorphous graphite in 1959. An amorphous graphite-like material was produced in Montana in the 1980s.

Deposits of this type occur at a number of places in the Grenville Series in northern New York, southwestern Quebec, and southeastern Ontario. Small deposits west and northwest of Ticonderoga, New York, were worked between 1850 and 1900. They consist of fine-to-coarse flake graphite irregularly concentrated in silicified marble adjacent to bodies of pegmatite.

Canada is endowed with a sizeable number of flake graphite deposits, most in Quebec or Ontario. These deposits are associated with Grenville Series marbles and gneisses. The largest producer is the mine and plant of Timcal Ltd. (formerly Stratmin, Inc.) at Lac-des-Iles, Quebec. Sequoia Minerals Inc. (formerly Mazarin, Inc.) has a good deposit at Fermont, Quebec, currently undeveloped.

Timcal Ltd. operates an open-pit mine on reserves totaling 23.7 Mt averaging 7.5% graphite. With this feed, the company produces as much as 25 kt of concentrate with 92%–98% graphite. Stratmin operated the Asbury Graphite Inc. mine and mill nearby for several years before closure. In November 1988, Stratmin leased the Asbury Graphite operation and contracted to supply Asbury with at least 10 kt of graphite each year for 5 years.

Sequoia (as Mazarin) extensively drilled its Fermont deposit and estimates that its reserves for the first 20 years of mining will total 3 Mt, averaging 17% graphite. Additional reserves total 5.8 Mt, averaging 14.2% graphite. The deposit has good access and is near the railroad running to the iron ore towns of Quebec from Sept Iles.

TECHNOLOGY

Exploration, Drilling, and Testing

Prospecting consists primarily of outcrop examination, trenching, and sampling, usually followed by drilling. A local non-technical person usually makes the initial discovery. In Mexico, a cowboy, shepherd, or local farmer may have found a showing of amorphous graphite. Any associated coal may even have been crudely mined and used locally as a fuel. In Madagascar or Brazil, a local hunter or palm-tapper may have come across a showing of crystalline flake graphite, which is not difficult in Madagascar where almost one-third of that huge island is underlain by graphitic rock or soil. Sri Lankan lump graphite has been known far back into history. Because of the high electrical conductivity of graphite, geophysical methods such as resistivity and self-potential have been used in the search for deposits in certain countries. Occasionally, the initial discovery was made by a government geologist doing routine field work. The Lac Knife deposit was discovered by a Quebec government geologist doing field work in 1959. When serious interest developed, Mazarin started trenching by shovel in 1987, stripped by bulldozer in 1988, and systematically diamond drilled more than 99 holes in 1989. This exploration, drilling, and testing of the Lac Knife crystalline flake graphite deposit is a good example of what the norm will be in the future, displacing the local non-technical person finding a graphite showing.

Mining Methods and Haulage

From 1890 to 1920, underground mining of graphite was practiced in New York and Pennsylvania. From 1942 until the end of World War II, only the open-pit methods were used, because working weathered rock was relatively easy. Graphite was mined underground at Dillon, Montana, during World War II, but shortly thereafter mining ceased because it was too costly to compete with Sri Lankan graphite.

Madagascar operations are entirely open pit, but in Bavaria, Korea, Mexico, and Sri Lanka, because of the depth and physical characteristics of the deposits, underground mining is practiced.

Mexican underground mining operations are 100–400 m below the surface, measured on the angle of the vein. Some of the older mines in Sri Lanka reached depths in excess of 450 m on a vertical plane. For many years, mining operations in Sri Lanka were primitive and ore extraction was slow and cumbersome. The mines were mechanized after World War II.

Madagascar operations also were primitive because low labor costs prohibited mechanization. After 1938 the mines began to use mechanical equipment to remove the overburden, and bulldozers and tractors easily removed the graphite-bearing schists.

Processing and Beneficiation

In Sri Lanka, graphite ore is extracted in lumps and hand-cobbed on a sorting patio to remove quartz inclusions. The finished product is graded as (1) large lump, 97%–99% carbon; (2) ordinary lump, 94%–96% carbon; (3) ordinary lump, 90% carbon; (4) chips, 85%–90% carbon; and (5) chippy dust, 80% carbon. The chippy dust and flying dust grade, however, are not produced in any quantity today.

In Madagascar the crude ore averages 10%–12% carbon. It is crushed by a primary crusher and then conveyed to a series of roll crushers and classifiers to remove the oversized and gangue material. The –6.35-mm product is then passed to flotation rougher cells, which separate the graphite flakes from the clay and sand. The product of the rougher cells passes to the finishing cells where each particle of graphite is recovered by means of a pine oil frothing process. This yields an 80%–84% carbon concentrate, which is dried; an y

residual pine oil is volatilized. The run-of-mill product is upgraded by mechanical means, such as rod mill grinding, to 0.3 mm sieve with 85%–90% carbon. Re grinding and flotation obtain higher carbon concentrates (up to 95%).

At the mill of Graphitwerk Kropfmühl S.A., in Bavaria, crude ores carrying 15%–20% carbon are crushed, passed through a grinding system, and then a rod mill, which reduces the ore to 40 mesh. This product is fed to a series of flotation and grinding steps, and the graphite concentrate is filtered and kiln dried with the final product averaging 90%–93% carbon. For further refinement, this product is milled and screened, producing grades with 95%–97% carbon.

These operations are fairly typical of those found in other countries. Some companies make high-purity graphite by leaching concentrate with strong acids or alkalis.

MARKETING

Graphite is used commercially in a number of applications, described in the sections that follow.

Batteries

Battery makers aggressively compete for available sources of natural graphite, synthetic graphite powder, and other forms of carbon. Carbon, not graphite, is almost always used in older batteries. Alkaline batteries will usually use some kind of graphite. The lightweight, rechargeable lithium ion batteries, typically used in cell phones and digital cameras, use a specialized graphite or a high-tech mesocarbon. Fuel cells are not included here but are in the section on Outlook that follows with other potential uses.

Bearings

Graphite is used extensively in bearings, and varies depending on the type of bearings being produced. This is a small-use market with limited growth potential.

Brake Linings

Graphite consumption as an asbestos substitute increased greatly in the 1980s when the dangers of asbestos were recognized. Graphite is particularly useful in brake linings for heavy-duty vehicles as opposed to passenger vehicles. As long as organic friction materials impregnated with graphite are used and accepted as satisfactory, graphite consumption should increase gradually in accordance with the increased number of vehicles on the road.

Carbon Brushes and Other Electrical Uses

Natural graphite encounters considerable competition from artificial graphite for this use. Wherever artificial graphite has advantages, it has already captured the market. For example, in the production of sliding contacts, the ash content variation in natural graphite has proved unacceptable; now artificial graphite in which the abrasive materials can be controlled is being used.

Crucibles

Crystalline flake graphite consumption to make crucibles has been steadily declining in market share over the last decade. Advances in crucible manufacturing technology now allow much greater flexibility in type and flake size of the graphite utilized.

Expanded Graphite

This use has been growing rapidly until fairly recently. Expanded graphite is used to make high performance gasket material for use at high temperatures or pressures and with radioactive or corrosive fluids. Expanded graphite can be made into a foil laminate that is

used in valve packings and as a gasket material. Foil can also be made into a heat sink for high-tech computer and communication products. Expanded graphite is being used as a hot topping compound to insulate hot ingots and decrease heat loss. Expanded graphite is made from crystalline flake graphite by treating it initially with chromic acid, followed by sulfuric acid, to weaken the bonds between the graphite flakes. The graphite is then heated to drive off the water, causing expansion, creating a product with properties similar to vermiculite.

Foundries

Foundries are one of the largest consumers of graphite. Graphite has a number of uses in foundries, but the largest single use is as a foundry facing or mold wash that allows the metal casting to be easily removed from the mold on cooling. Another significant use is as a carbon raiser, when a carbonaceous material is added to hot metal to raise its carbon content. Graphite is also used to lubricate extrusion dies before hot metal is reshaped to form other products.

Lubricants

This market is tremendously complex because of the variety of lubricating jobs that must be done and the myriad lubricant types that are available. Graphite has been an important lubricant and probably will continue to be, but competition is stiff. Graphite added to a soapy lubricant is considered to be a good die lubricant, particularly for galvanized wire, though the discoloration it produces is not desirable. Natural graphite is a good antiseize agent in steel mill and railroad applications because it creates a solid lubricant film that retains its properties under pressure and high temperature. In this particular use, the customer specifies the graphite content empirically, so its use may not be based on some theoretical factor(s). Natural graphite is used in applications in which the siliceous portion of the natural graphite is overshadowed by the background contamination of dirt and sand, for example, gear lubrication for mining machinery.

Graphite of colloidal size dispersed in kerosene, oil, or another carrier is used when a quick-drying film is desired in high-temperature lubricating jobs (i.e., conveyors passing through ovens).

Packings

Fine flake graphite performs well with oils or greases because it resists temperatures up to 310°C. Closely controlled particle size is less important for packing use. Graphite use will tend to remain relatively steady, but may decline in more modern equipment that no longer uses older style packings. Very small quantities of molybdenum also offer excellent lubricating qualities.

Pencils

Low-cost improvements in the pencil industry have led to greater jetness, higher carbon content, smaller particle sizes, and more unctuousness and opaqueness in the graphite. However, technology improvements must not add to the cost of graphite for the pencil manufacturer. Imported pencil leads from China now have most of the pencil market.

Refractories

Graphite is used in both plastic (castable) refractories, principally in ramming and gunning mixes, and shaped refractories, principally carbon-magnesite brick and alumina-graphite continuous casting ware. For the last 20 years, graphite-containing refractories have increased their market share against other refractories as the demand for high-performance ware has grown, principally for

products that resist high temperature, thermal shock, and corrosion. The steel industry consumes around 70% of refractories worldwide.

Gunning and ramming mixes, used where the refractory must be deformable or flexible, commonly use amorphous graphite. Carbon-magnesite mixes are made from crystalline flake graphite.

Carbon-magnesite brick is used to line basic oxygen converters, in the slag lines and water-cooled sidewalls of electric arc furnaces, and to make steel ladles. Graphite consumption in the former two uses grew rapidly in the 1980s, and consumption in the latter use grew more in later years. Use in basic oxygen converters is still growing in some countries.

Continuous casting wears made of alumina graphite includes items such as shrouds, subentry tubes, and stopper rods.

Graphite Grades and Specifications

As described earlier, the two main categories of natural graphite are known commercially as crystalline and amorphous, even though all graphite is truly crystalline and the distinction is only one of crystal size. "Amorphous," as applied to graphite, has been further complicated by longstanding industrial application of the term to very fine particles of crystalline flake graphite that can be sold only for low-value uses, such as foundry facings. This very fine flake is also called crystalline dust. Fine-grained varieties of lump graphite that can be reduced easily to fine particle size by grinding are called amorphous lump. This distinguishes them from tough, platy, and acicular varieties, known as crystalline lump, that can be reduced in particle size with difficulty. Thus, large quantities of fine-crystalline flake graphite are imported under the amorphous classification.

Sri Lankan lump graphite is classified either as amorphous or crystalline. Each type is divided into a number of grades, depending on the particle size (lump, ranging from the size of walnuts to that of peas; chip, from the size of peas to about that of wheat grains; dust, finer than 60 mesh), graphite carbon content, and degree of consolidation.

Amorphous graphite is graded primarily on graphitic carbon content. Commercial products contain about 50%–94% carbon, depending on their source.

Crystalline flake graphite from Madagascar is divided into two main grades, flake (coarse flake) and fines (fine flake). Madagascar crucible flake must have a minimum of 85% carbon and be in the size range –8 to +60 mesh. Other crystalline flake graphite is graded according to graphitic carbon content and particle size.

The synthetic graphites generally are classified as electrodes, anodes, molded shapes, and powders or scrap, and they are made from petroleum coke and pitch. Graphite fiber is made from textile threads or extruded pitch fibers.

Graphite Prices and Pricing

Graphite pricing behavior is rather complex, mostly because graphite is not traded on any commodity exchange. Graphite prices are subject to negotiation between buyer and seller, and depend on carbon content, flake size and distribution (for crystalline flake), and the identity and nature of any impurities. The product is usually customized for the individual consumer. China has been the world price setter for the last 20 to 30 years, sometimes competing with other nations and at times through interprovincial competition within the country itself.

Three price series for natural graphite are detailed here: (1) crystalline flake, which has become the major competitor in the last decade or so; (2) Mexican amorphous, which is currently in a long-term decline in importance because low-tech end uses are becoming obsolete; and (3) Sri Lankan lump graphite, which is a specialty product because its relatively high price results in a low demand.

Crystalline flake of various sorts is the most important natural graphite and accounts for 80%–90% of the value of U.S. imports. There are posted prices that have not changed for many years. The USGS price for crystalline flake was US\$615 per ton in 2000, US\$520 per ton in 2001, US\$565 per ton in 2002, and US\$560 per ton in 2003; the price for Sri Lankan lump and chip was US\$1,250 per ton in 2000, US\$1,360 per ton in 2001, US\$1,220 per ton in 2002, and US\$1,200 per ton in 2003; the price for amorphous was US\$130 per ton in 2000, US\$131 per ton in 2001, US\$115 per ton in 2002, and US\$120 per ton in 2003. Industry observers have said that even the USGS prices have been subject to substantial discounting in the 2000–2003 period of collapsing demand.

Substitutes for Graphite

The most common substitutes for graphite are other forms of carbon. In steelmaking, petroleum coke, anthracite, and used (synthetic) graphite electrode scrap can be used as a carbon raiser instead of natural graphite. Calcined coke and other carbons can be used in certain foundry core and mold washes instead of natural graphite. Synthetic graphite powders are often substituted for natural graphite, depending on relative price.

Noncarbon substitutes for natural graphite include molybdenum disulfide for lubricant use. Graphite is substituted for asbestos in automotive brake linings and is being substituted for by certain organic nongraphite compositions. Alternate nongraphite refractory compositions, such as silicon-carbide or chrome-containing compositions, can substitute for carbon-magnesite bricks, alumina-graphite shapes, and crucibles.

Packaging and Shipping

The cost of shipping graphite is a major cost consideration for the customer. Because graphite is messy, it must travel bagged or in closed containers. The most common form of packaging is 1-ton "supersacks"; of lesser importance are 25-kg bags of paper or plastic. Burlap bags were commonly used in the past but are now rarely used. Supersacks are made of woven polypropylene and measure 88.9 cm × 88.9 cm × 190.5 cm. For example, amorphous graphite coming from Mexico as lumps commonly were shipped in covered hopper rail cars; fines were transported in bags. Most of the graphite imports now come by ocean freighter as a large shipment with other bulk materials, or as general freight if the shipment is small. Inside the United States, graphite is transported by barge, truck, or rail, depending on port of origin and final destination.

ECONOMIC OR COMPETITIVE FACTORS

Import Duties

U.S. imports of natural graphite as of December 31, 2003, are duty-free for HTS (Harmonized Tariff Schedule) categories 2504.10.1000 and 2504.90.0000. This applies to all nations except Cuba and North Korea.

Graphite By-products or Coproducts

Graphite deposits have been mined exclusively for their graphite content and that practice will continue. In the past, proposals to recover graphite and coproduct mica from a graphite-mica schist and another to recover graphite and gold were considered; however, neither proved to be economically viable.

Depletion Allowance, Costs, and Timing

The U.S. depletion allowance for tax purposes is 22% for domestic lump and amorphous graphite, and 14% on domestic crystalline flake. Because the United States has no domestic reserves and only

small, low-grade resources, there is almost no likelihood of any domestic producer starting production and claiming this allowance. Similarly, questions of costs and timing of domestic production are not likely to arise.

Regulatory and Environmental Considerations

The environmental requirements for natural graphite, which is an inert, nontoxic substance, are limited to dust control and control of organic vapors that may arise in making certain graphite products from imported graphite. Given the current and future absence of graphite mining, no other requirements will be applicable.

OUTLOOK AND FUTURE TRENDS

In the last 4 to 5 years, graphite has lost the majority of its most important market in the United States—refractory use. The 2004 outlook was primarily based on the *Graphite Advocate News* Web site (www.basicsmines.com/graphite), which is updated frequently, and the USGS Web site (<http://minerals.usgs.gov/minerals/>), which is updated two times per year. After several negative years, the positive 2004 outlook reflected a strong U.S. metal-using economy and strongly expanding Chinese domestic natural graphite demand, mostly from the Chinese steel industry. China is poised to become a net importer of natural graphite and will slow down or stop exporting altogether, but this could be temporary or sporadic because Chinese reserves would easily support new mines and additional production. The Chinese steel industry is growing rapidly; Chinese steel production in 1999 was 124 Mt and rose to 200 Mt in 2003. Overall, U.S. graphite sales in 2003 were flat, down 2% from 2002. Graphite sales in 2004 were up 2%–5% from 2003.

Long-Term Shift in Consumption by End Use

Major shifts in U.S. consumption of natural graphite by end use are under way. Graphite consumption in refractories was 11,000 t in 2000 (the latest full set of end-use data) but has dropped to a fraction of former consumption because many U.S. refractory plants have closed, carbon-magnesite bricks have been replaced with monolithics, and U.S. carbon-magnesite brick has been replaced by Chinese imports. Consumption in brake linings was 6,600 t in 2000 but will erode because of new nongraphite-containing (nonasbestos organic or NAO) brake lining formulations. Consumption in expanded graphite/foil/packings was 5,000 t in 2000, which might grow in a few submarkets but otherwise should not grow. Consumption in batteries was 4,000 t in 2000 but should be able to maintain itself in spite of fierce competition from other natural and synthetic carbon materials. Consumption in foundry uses, mostly mold washes, was 3,000 t in 2000 and depends on the future of the foundry industry as other material-shaping techniques come in to use. Graphite use in lubricants was 1,600 t in 2000 and should be stable or maintain slow growth at that level. High-volume use in fuel cells may occur in the longer term. Graphite foil use in heat sinks may become significant.

Short-Term Outlook

Graphite-Based Refractories

Natural graphite (mostly flake) is used in carbon-magnesite brick and in alumina-graphite shapes, with smaller amounts in crucibles, gunning and ramming mixes, and other kinds of refractories. The bricks are used to line basic oxygen steel converters and electric-arc furnaces to withstand extreme conditions (temperature, corrosion, etc.). The shapes are used as continuous casting ware usually in the form of nozzles to guide molten steel from ladle to mold. Consumption for refractories in 2003 dropped 10% from 2002; major

graphite suppliers have left this market. Future demand for carbon-magnesite bricks will most likely be met by imports from China.

Fuel Cells and Heat Sinks

These are potential high-growth, large-volume graphite (natural and synthetic) end uses, but are currently a very small part of consumption. Large volumes of graphite will not be consumed in these end uses for many years.

Brake Linings

Natural graphite (amorphous and fine flake) is used as a substitute for asbestos in brake linings for heavier (nonautomotive) vehicles. The 2003 consumption was up about 2%–3% from 2002.

Graphite Powder (Synthetic)

Graphite powder is mostly used as a carbon-containing additive put in molten steel to raise the carbon content in brake linings, and in packings, seals, batteries, and other minor uses. Synthetic graphite powder production in 2001 was 95,000 t (latest USGS data). USGS data show that imports run 25,000–30,000 t and exports 60,000–70,000 t. The demand for powder in 2003 increased 20% from 2002 in volume.

Lesser End Uses

Lesser applications include use in lubricants, powdered metals, foundry facings, plastics, rubber, and pencils. The growth markets in this category are in rubber and in plastics (including styrofoam coatings). The weakest market for graphite is in pencils, which has almost disappeared; pencil leads now are imported directly from China.

Gypsum and Anhydrite

Roger Sharpe and Greg Cork

INTRODUCTION

Gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$) is a versatile mineral with hundreds of uses. The predominant use of gypsum since ancient times has been as a construction material. According to Schroeder (1970), gypsum was used as a mortar in the Egyptian pyramids in 3000 BC, and Pressler (1985) indicated that at the burning or calcining of gypsum was described by the early Greeks. Gypsum mortar was used in Egypt during construction of the Pyramid of Cheops in the 18th Dynasty (1580–1350 BC). Hydraulic gypsum mortar was used in medieval times in castles and fortresses in what today is Germany. Remnants of walls constructed with hydraulic gypsum mortar have existed for centuries in the Hartz Mountain region of Germany (Wilder 1918).

The development of gypsum plasters is difficult to trace; by the late 1800s, however, a commercial process had been developed to slow the setting time, thereby allowing widespread use of finishing plaster. Prefabricated wallboard panels were developed in 1918 (Adams 1991) but were not widely used until the great construction boom after World War II. Before that time, plastered walls were more common in residential and commercial construction.

Worldwide, the predominant use of gypsum is in the manufacture of construction plasters and portland cement (anhydrite, most commonly used in the manufacture of portland cement, is often sold as a mixture of impure gypsum and anhydrite). The predominant use of gypsum in North America, however, is in various types of wallboard panels. In 2003, about 90% of the total gypsum produced in the United States was used in wallboard and construction plasters.

Gypsum has been used in agriculture as a soil amendment since the middle of the eighteenth century. The earliest accounts of gypsum's agricultural applications were published in Switzerland in 1768. George Washington and Benjamin Franklin were proponents of the use of gypsum in agriculture in the United States in the late 1700s. Benjamin Franklin promoted the use of gypsum by applying ground gypsum, commonly known as "land plaster," to a field of clover in a pattern forming the phrase "Land Plaster Used Here" (Wilder 1918). The clover grew thicker and greener in the areas where gypsum was applied.

Specialized methods of calcination of gypsum and for mulation with additives allow for manufacturing of more than 400 products. Uses vary from simple ground gypsum in agriculture to specialized plaster products in art and statuary; medical applications; intricate cast architectural detail; and fast-setting, high-strength construction products. There is no recognized commodity

value of a ton of raw gypsum. Although mining costs are relatively low, the energy-intensive postmining processing and ultimate end use add significant value to the products made from the gypsum. Freight costs are a significant factor in marketability of a gypsum deposit.

Synthetic gypsum, derived primarily from environmental controls on coal-fired power plants by a process known as flue gas desulfurization (FGD), has become a significant raw material resource used in the manufacture of gypsum wallboard products. Demand for synthetic gypsum has steadily grown since the 1980s, and in 2003 about 26% of the total gypsum used for manufacturing wallboard in the United States was synthetic. Originally thought of as a waste product from the environmental controls on coal-fired power plants requiring disposal in landfills, technological improvements allowed synthetic gypsum to become a marketable coproduct. Many of the wallboard plants in the United States built since the late 1990s use only synthetic gypsum as a raw material.

Gypsum deposits are distributed throughout much of the world, and gypsum is produced in more than 90 countries (USGS 2004). The value of a deposit of gypsum depends on geological, mining, engineering, and other factors in order to be used economically.

The utility and value of a gypsum deposit can change over time as technological innovations in mining and manufacturing occur and new products are developed. Factors that must be considered when evaluating a gypsum resource for potential development, mining, manufacturing, and marketing include the following:

- Proximity to market area—because gypsum has a low unit value, an ideal deposit of gypsum would be located within the heart of a growing metropolitan area
- Transportation—shipment of raw and finished materials by truck, train, ship, or barge; import of paper used in wallboard manufacturing; transportation of finished products to jobsites, distributors, and retail outlets; potential for backhauls of raw materials or finished products
- Fuel and utilities—wallboard manufacturing is highly energy intensive and requires an infrastructure of electrical service and a source of fuel for calcination and drying of wallboard panels
- Water—the availability of process water is essential for the manufacturing of wallboard products but not for plaster, portland cement rock, or agricultural gypsum

Table 1. World gypsum production, 2002–2003

Country	Production, kt	
	2002	2003*
United States	15,700	16,000

PRODUCTION AND TRADE

The United States is both the largest producer of gypsum (Table 1) and the largest consumer of products manufactured from gypsum in the world. Canada and Mexico are significant producers, and the majority of their production is exported to the United States. Thailand and Spain are also significant exporters of gypsum. Almost two thirds (63%) of the total world production of gypsum in 2003 came from seven countries: United States (15.7%), Iran (11.3%), Canada (8.8%), Spain (7.4%), China (6.8%), Mexico (6.7%), and Thailand (6.4%).

United States

Gypsum wallboard manufacturers in the United States shipped 2.93 billion m² of wallboard products in 2003. The wallboard manufacturing industry is cyclical. Production in the United States and Canada peaked in 1999, declined in 2000, and increased from 2001 to 2003.

The total amount of gypsum consumed in the United States in 2003 was 33 Mt. Mining of natural gypsum amounted to 16 Mt.

Approximately 28.8% of the total gypsum demand, 9.5 Mt, was supplied by synthetic gypsum. Imports of foreign gypsum totaled 8.3 Mt, with Canada supplying almost 69% (Table 2). Manufacturing of gypsum wallboard and plaster products accounted for about 90% of the total amount of gypsum consumed in 2003. About 2.62 Mt were used in portland cement production. Agricultural applications accounted for about 1.0 Mt.

Iran

Iran is the second largest producer of gypsum products in the world, exceeded only by the United States (USGS 2004). In 2002, Iran produced about 11.5 Mt of gypsum and exported about \$5.7 million worth (Hobbs 2002). Approximately 60% of the total annual production is estimated to be in the manufacture of construction plaster. Portland cement production in Iran during 2002 was about 30 Mt, and it is estimated that 1.5 Mt of gypsum was consumed in the manufacturing of portland cement, based on a usage of about 5% gypsum by weight.

Canada

The world's third largest producer of gypsum is Canada. There are 11 wallboard manufacturing plants in Canada, but a significant proportion of gypsum is exported to plants along the east coast of the United States. Canadian gypsum imported into the United States during 2003 was about 5.7 Mt, representing about 17% of the total consumption. Gypsum is produced in the provinces of Newfoundland, Nova Scotia, Ontario, Manitoba, and British Columbia.

The majority of Canada's production comes from Nova Scotia; National Gypsum Canada Ltd. operates the world's largest gypsum quarry at Milford Station, near Halifax. Fundy Gypsum Company and Little Narrows Gypsum, subsidiaries of U.S. Gypsum (USG), operate two large quarrying operations in Nova Scotia for export to the United States and external portland cement rock customers. There is only one active underground gypsum mining operation in Canada, located at Hagersville, Ontario, and operated by Canadian Gypsum Company Ltd., a subsidiary of USG.

Spain

Spain has abundant resources of gypsum located predominantly in the eastern half of the country and the Balearic Islands of Mallorca, Ibiza, and Menorca. Abundant gypsum resources occur along the Mediterranean coast between Gibraltar and eastward to the French border. Iberyeso is the largest producer in the country.

The Triassic-age gypsum deposits are significant in terms of reserves, quality, and minability (Regueiro and Barros 1995). In most cases, Triassic-age gypsum deposits have a gypsum purity of 93% to 96%. Tertiary-age gypsum deposits are significant in terms of the economic potential, continuity, thickness, and quality. Eocene deposits are relatively rare, but Oligocene-age deposits are extensive, have a high purity, favorable geographical locations, and ease of exploitation. Abundant Miocene–Pliocene-age gypsum deposits occur in the Alicante Area, between Almeria and Alicante. The gypsum has a high quality (about 94% purity) and is interbedded with marl. Studies by the Spanish government identified 77 large deposits with purities ranging from 70% to 96% and resources of more than 20 billion t.

China

The annual production of gypsum for all uses in China is about 11 to 12 Mt, primarily from the provinces of Shandong, Hubei, Jiangsu, Hunan, Shanxi, Sichuan, and Gansu. O'Driscoll (1994) reported 54 state-operated mines and approximately 100 privately

operated mines in 16 provinces. The major gypsum mining operations in China include Pingyi and Tai'an in Shandong Province and Yingcheng in Hubei Province. About 65% of China's gypsum resources occur in Shandong Province. Gypsum deposits in Hubei and Hunan provinces provide high-purity gypsum to the growing market for industrial gypsum products in the cities of Guangzhou and Shanghai. The gypsum resources in China are widely distributed and immense, with reserves estimated to be in the billions of metric tons. The reported reserves vary from 57 to 100 billion t. In the mid-1990s, gypsum reserves of 114 billion t were identified in Hubei Province alone.

The gypsum deposits in China are highly variable in the areal extent, in thickness, and in quality. The gypsum occurs as thin seams of fiber gypsum (satin spar), flake gypsum (selenite), and rock gypsum. Depth of the deposits varies from very shallow to about 600 m. Gypsum-bearing sequences from a few centimeters to more than 100 m in thickness occur throughout the country.

The mining and processing of gypsum in China are labor intensive. Underground mining is generally accomplished by manual methods such as sorting ore from waste, loading ore cars with gypsum, and tramping the cars to incline or shaft stations. Waste rock is hand-stacked to provide roof support. The gypsum is sorted at the surface into stockpiles of different grades depending on purity and end use. *Snow gypsum* is the term used often for white rock gypsum, and *fiber gypsum* is the term used for very pure satin spar gypsum.

Snow and fiber gypsums are used for the manufacture of ceramic plasters (sanitary and dinnerware), dental and orthopedic plasters, art plasters, chalk, glass-reinforced gypsum ceiling panels, and decorative architectural details such as cornices. Some plaster is produced for the brewery and tofu industries.

Mexico

Gypsum is mined in the following states in Mexico: Nuevo Leon, Coahuila, Colima, Chihuahua, Sonora, Puebla, Oaxaca, Jalisco, and Baja California del Sur. A significant amount of gypsum in Mexico is used internally in the manufacture of portland cement. Mexico is a significant exporter of gypsum to the Pacific coast of the United States and periodically to Pacific Rim countries such as Japan. Exports to the United States in 2003 were about 1.8 Mt.

The majority of gypsum exports are produced from two quarrying operations in Baja California del Sur. COMSA, on San Marcos Island in the Sea of Cortez, and CAOPAS, just north of the town of Santa Rosalia, provide the majority of gypsum to wallboard plants on the Pacific coast of the United States.

Numerous small gypsum plaster calcining facilities, known as *yerasas*, are distributed throughout Mexico. Yerasas manufacture construction plasters for local markets and vary in size from crude beehive kilns to relatively modern calcining operations.

Gypsum wallboard is currently manufactured at only three sites in Mexico. One plant is located in Puebla, about 120 km southeast of Mexico City, and two are near Monterrey, Nuevo Leon State, in northern Mexico.

GEOLOGY

The most common sulfate minerals are gypsum and anhydrite, which are formed from diverse origins. Gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$) is primarily formed as a chemically precipitated sedimentary rock in basin or sabkha environments, but it may also form as the result of solutional, karst, hydrothermal, and volcanogenic processes. Table 3 shows the chemical composition of gypsum and anhydrite. Anhydrite (CaSO_4) is the anhydrous form of the calcium sulfate family of minerals. Anhydrite may form as a primary mineral in a sabkha

Table 3. Chemical composition of gypsum and anhydrite, %

Mineral	Formula	Lime (CaO)	Sulfur Trioxide (SO ₃)	Water of Crystallization (H ₂ O)
Gypsum	$\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$	32.6	46.5	20.9
Anhydrite	CaSO_4	41.2	58.8	0.0

depositional environment or deep-basin environments. The terms *gypsum* and *anhydrite* are commonly used interchangeably for the minerals and rocks that are composed primarily of these minerals.

Gypsum and anhydrite may be deposited simultaneously in a sedimentary environment and are easily converted from one to another under varying conditions of heat, pressure, and the presence of water. The occurrence and relationship of anhydrite and gypsum in a deposit is complex. Mineralogical, textural, cross-cutting relationships and microscopic examination may be necessary to determine the ultimate origin of anhydrite in a deposit. Some deposits exhibit multiple episodes of conversion from gypsum to anhydrite and vice versa.

Mineralogy

Gypsum forms monoclinic crystals with a perfect {010} cleavage and distinct cleavages along {100} and {101}. It is distinguishable from anhydrite by its lower Mohs hardness (2.0 versus 3.5) and specific gravity (2.24 versus 2.97 g/cm³). Pure gypsum is colorless, but may be tinted yellow, red, and brown because of the presence of impurities. Twinning is common along {100}, forming "swallowtail twins." Gypsum is relatively soluble in fresh water (about 0.2 g/100 g H₂O) and is easily dissolved or eroded in conditions of high humidity or rainfall.

Anhydrite forms orthorhombic crystals with perfect cleavages along {100} and {010} and a good cleavage along {001}. Anhydrite has a Mohs hardness of 3.5 and a specific gravity of 2.97 g/cm³. Pure anhydrite is colorless, but the color is variable from colorless to dark gray.

Lithology

Commercial deposits of gypsum may be almost pure or contain variable amounts of syndepositional impurities such as limestone, dolomite, clay, anhydrite, and soluble salts of potassium, sodium, and magnesium. Primary gypsum deposits consist of rock gypsum and alabaster. Selenite, satin spar, and gypsite are secondary varieties of gypsum. Anhydrite may occur as either primary or secondary minerals in a deposit, depending on its geological history.

Petrographically, most rock gypsum has a medium to coarse crystalline texture. Some deposits contain coarse crystalline gypsum poikiloblasts. Gypsum in the Upper Miocene Boleo Formation in Baja California del Sur, Mexico, contains euhedral selenite crystals up to about 25 cm in width. The Mississippian Windsor Group in Nova Scotia, Canada, contains abundant scattered poikiloblasts.

Petrographically, anhydrite has a massive or granular texture. Scattered gypsum crystals commonly occur in the anhydrite groundmass and increase near the gypsum-anhydrite contact. Complex hydrous salts of sodium, potassium, and magnesium sulfate commonly occur in conjunction with anhydrite and are concentrated in the gypsum near the contact.

Alabaster

Alabaster is a compact, fine-crystalline, translucent variety of primary gypsum that has been used by artists to produce statuary for thousands of years. Typically found in a variety of colors depending

on the type and amount of impurities present, alabaster generally occurs as zones within larger gypsum deposits.

Selenite

Large, clear, euhedral crystals of gypsum are known as selenite. Bladed selenite crystals commonly form in fluid-filled cavities. Selenite may also form along fault zones. Cleavage fragments may be mistaken for muscovite mica. Poikilitic masses of selenite crystals, commonly known as “gypsum roses,” are formed by the crystallization of gypsum from interstitial pore fluid in unconsolidated sand.

Possibly the largest selenite crystals in the world are located in Chihuahua State, Mexico. The Cave of Swords (La Cueva de las Espadas) has been well known since 1910 for the large-bladed selenite crystals. In 2000, however, a cavity containing enormous selenite crystals was discovered in the Naica underground silver and lead mine operated by Industriales Peñoles, SA de CV. The cavity was encountered at a depth of about 300 m and has dimensions of about 9 m by 18 m. The temperature in the cavity is up to 65°C with 100% humidity. Selenite crystals with a diameter of 1.2 m and up to 15 m in length occur in the cavity.

The Lechuguilla Cave complex, located near Carlsbad Caverns, New Mexico, contains large selenite speleothems. The caves are believed to have been formed at the groundwater table by the reaction of groundwater with sulfur dioxide rising from deeper natural gas deposits, producing sulfuric acid. The sulfuric acid dissolved the limestone forming very large openings and extensive speleothems.

Satin Spar

Satin spar is a fibrous variety of needle-shaped gypsum crystals filling fractures or along bedding planes. The needle-shaped gypsum crystals form with the C-axis oriented at a steep angle or perpendicular to the vein walls in fractured rocks undergoing deformation. The orientation and steepness of the crystals define the direction and amount of strain, such as dilation or shearing. It is important to recognize that satin spar is not an asbestiform mineral. The stresses may be caused by regional tectonism or induced in the rock by the hydration of anhydrite to gypsum. During hydration anhydrite undergoes a volumetric increase of 26% and may induce stresses of 2 to 69 MPa.

Satin spar is mined in China for use in the manufacture of gypsum plasters. Conco rdant, horizontally oriented veins of gypsum up to 0.5 m thick are interbedded with shale. The satin spar is mined and sorted by hand to produce an extremely pure product.

Gypsite

Gypsite is an earthy, pulverulent variety of gypsum that forms a surficial deposit in shallow saline lakes, playas, and salt pans in arid environments. The calcium and sulfur required to form gypsum are derived from the erosion and weathering of rocks and transported in surface and groundwater to closed basins. Gypsum precipitates at the surface by capillary movement and evaporation of groundwater. Since gypsum is less soluble than halite a crust of gypsite forms over the soft beds of halite. Gypsite is often contaminated by wind-blown sand or silt and clay from periodic flooding of the playas.

Rock Gypsum

The most common variety of the mineral is known as rock gypsum. Rock gypsum commonly consists of aggregates of gypsum crystals interbedded or mixed with mudstone, shale, siltstone, limestone, or dolomite. Gypsum rock and anhydrite may be nodular, massive, laminated, or bedded. The primary sedimentary structures in gypsum and anhydrite deposits are associated with the depositional

model and the proximity to terrigenous detritus. The Fish Creek Gypsum in California contains trace amounts of biotite mica. The Permian Castile formation, deposited in the Delaware Basin of Texas and New Mexico, contains well-laminated anhydrite with varves of organic matter and calcite that have correlated over a distance of more than 100 km (Blatt, Middleton, and Murray 1980). The evaporites were deposited in a standing, deep body of water. Alternatively, in a sabkha environment, gypsum and anhydrite form by the nucleation and growth of crystal masses from pore fluids within soft, unconsolidated tidal-flat sediments, consisting of terrigenous or carbonate mud. Nodular masses grow and displace the surrounding host sediments, forming a “chickenwire” texture. Gypsum may be precipitated within more rigid host sediments of clay or sand and form large poikilitic crystals that encase the host sediment. The Mississippian Maccrady Formation in southwestern Virginia contains gypsiferous mudstone with poikilitic gypsum crystal faces up to 50 cm exposed in underground mine workings.

Anhydrite

Anhydrite may form as a primary mineral in a sabkha depositional environment and deep basin, subaqueous deposits such as the Castile formation in the Delaware Basin. Gypsum may begin to dehydrate under the lithostatic loading below a depth of burial of about 600 m and transform into anhydrite. Subsequent uplift or erosion of overlying rocks decreases the lithostatic load, allows the percolation of groundwater through fractures and along bedding planes, and rehydrates the anhydrite to gypsum. Some deposits, such as the Devonian Wapsipinicon Formation in southeastern Iowa, exhibit evidence of several cycles of dehydration and rehydration. The gypsum-anhydrite contact is subhorizontal and the anhydrite cuts across enterolithic folds in gypsum as the result of an earlier phase of hydration.

Impurities

Most gypsum is white to grayish white, although type and amount of impurities in any given deposit determines the color of the rock. The impurities may be intimately mixed with the gypsum because of primary sedimentary processes previously described, or be present as the result of the secondary effects of solution, weathering, and erosion.

The most common impurities in gypsum are carbonates, clay, anhydrite, and soluble salts. With certain limitations, carbonate and clay impurities may not be detrimental in the manufacture of gypsum wallboard, plasters, and agricultural gypsum. Portland cement rock is less sensitive to the presence of anhydrite or soluble salts. The minimum gypsum purity (percentage content of gypsum) for wallboard and other quality-control parameters are established by organizations such as the American Society for Testing and Materials (ASTM) and Underwriters Laboratories (UL).

Impurities may have little or no effect on the quality of products manufactured from gypsum. Certain types of impurities, such as soluble evaporite minerals or montmorillonite clays, may expand on hydration in humid environments.

Carbonate

Limestone, composed primarily of calcium carbonate, has relatively little effect on the manufacturing of wallboard, the predominant gypsum product. The most significant effect is to increase the weight of the wallboard, which affects the level of installation effort and freight costs. Dolomite is a detrimental impurity in industrial gypsum plaster used for the manufacture of ceramics, such as dishes, and sanitary ware, such as sinks and toilets. Dolomite has a higher specific gravity

than gypsum. Particles of dolomite in ceramic grade plaster sink to the bottom as the slurry is poured into molds. The dolomite particles form projections at the mold–cast interface; these projections leave surface pits in the product being cast.

Clay

Clay is the second most abundant impurity in gypsum deposits. Clay impurities may be present as a result of both primary and secondary depositional processes. Primary impurities of clay occur as laminae, thin interbeds, internodular matrices, and intraclasts within the gypsum. Nucleation and growth of gypsum or anhydrite nodules from interstitial fluids in soft terrigenous or carbonate mud forms an internodular matrix, leading to the chickenwire description of its texture. Postdepositional solutional and erosional processes commonly result in the presence of clay, sand, and organic impurities in fractures.

The type of clay mineral, particularly members of the smectite group, may have deleterious effects on the quality of wallboard products. Smectite group clays have an affinity for absorbing multiple molecules of water or other liquids and, thus, increase in volume. This characteristic is useful in the manufacture of cat litter or oil absorbent, but may be deleterious in the manufacture of gypsum wallboard. Soluble salts, primarily sulfates, and chlorides of potassium, magnesium, and sodium adsorb onto clay crystals.

If wallboard containing a high percentage of smectite clays or soluble salts is installed in a humid environment, hydration of these mineral species results in an increase in volume and may cause a quality defect known as “humidified split.” Humidified split occurs when soluble salts migrate to the gypsum core–paper interface and absorb multiple molecules of water from the atmosphere, forming complex salts and blisters on the surface of the wallboard. Alternatively, the volumetric expansion of the smectite clays may also produce humidified split.

Improper control of the calcining temperature of gypsum during the manufacturing process may result in an inaccurate determination of gypsum purity. Calcining at a temperature that is too high may begin to thermally dehydrate the clay, giving a false purity determination.

Anhydrite

Anhydrite is a common impurity in deposits of gypsum and may occur as a primary depositional mineral or the product of dehydration of deeply buried gypsum. Anhydrite can be found as a massive rock or as a mixture of gypsum and anhydrite in partially hydrated deposits. Soluble salts, such as sodium, magnesium and potassium chlorides, and sulfates are commonly concentrated in a halo in gypsum adjacent to the anhydrite contact. The soluble salts are leached from the anhydrite during hydration and precipitated in tensional features, such as fractures, many of which form during the volumetric expansion during hydration.

Anhydrite may be viewed either as a contaminant in a gypsum deposit or as a marketable coproduct. As a contaminant, the anhydrite is harder and denser than gypsum and contains higher levels of soluble salts. Anhydrite increases the weight of the finished wallboard products and is abrasive to grinding and processing equipment. As a coproduct, quarry-run anhydrite or a blend of gypsum and anhydrite may be used as a portland cement rock. Portland cement manufacturers use a variety of products from gypsum, anhydrite, or an anhydrite–gypsum blend, depending on the manufacturing process. The primary function of gypsum or anhydrite in portland cement is to control the setting time of the finished product. The SO_3 content of the portland cement rock is the most important quality parameter.

Soluble Salts

Gypsum deposits commonly contain soluble evaporite minerals, such as halite (NaCl); sylvite, (KCl); mirabilite ($\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$); and epsomite ($\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$). Soluble evaporite minerals may form during (1) evaporation of seawater in restricted basins; (2) late-stage diagenetic processes in sabkha environments; (3) gypsumification of anhydrite; or (4) leaching from interbedded clay. During the evaporation of sea water in a restricted depositional basin, excess sulfate ions not consumed in the formation of gypsum or anhydrite may combine with either magnesium or sodium to form epsomite and mirabilite, respectively. Sodium and potassium may combine with chlorine ions to form halite and sylvite, respectively.

In a sabkha environment, gypsum and anhydrite are formed by diagenetic processes within tidal-flat sediments. The pore-water chemistry changes as dolomitization of carbonate sediments occurs. Soluble evaporite mineral components can be released from fluid inclusions within carbonate crystals, or be included in a disordered crystal lattice. Mud-rich sabkhas contain clay crystals into which soluble salts may be adsorbed. During the conversion of anhydrite to gypsum, soluble salts are released and form an enriched halo in the gypsum near the anhydrite–gypsum contact. The volumetric expansion during the conversion provides fractures for the transport of saline fluids.

Soluble evaporite minerals are rarely directly observable in outcrops in humid environments or drill core because they are highly soluble in fresh water. In arid environments, gypsum outcrops may have an efflorescent crust of magnesium sulfate formed by the wicking of water by capillary action at the rock's surface and rapid evaporation. Very fine, acicular crystals of epsomite form on the floor and roof in some underground gypsum mines by the evaporation of humid air.

Calcium sulfate hemihydrate reacts with water to form gypsum–water slurry in the manufacturing of wallboard. Soluble evaporite mineral components in the slurry migrate to the gypsum–paper interface by capillary action. The installation of wallboard containing a high soluble-salt content in a humid environment may result in the formation of complex salts of sodium, potassium, and magnesium sulfate with up to 15 molecules of water in their crystal structures. The volumetric increase associated with the absorption of more than two molecules of water may result in the failure of the gypsum core–paper bond and the formation of blisters, known as “humidified split.”

Other Impurities

Yellow to red discoloration results from mud staining and the presence of iron oxides. Dark purple to black discoloration may be caused by the presence of manganese oxide, carbonaceous limestone, mafic rock fragments, or detrital minerals. The presence of copper or certain types of algae may stain gypsum a greenish color. In some deposits trace amounts of celestite (SrSO_4) may be present, and siliceous nodules are found in some deposits.

Bassanite

Bassanite is an unusual type of an impurity in a few gypsum deposits, notably in the Miocene Fish Creek Gypsum in California. Bassanite is a naturally occurring form of calcium sulfate hemihydrate that forms from the interaction of hydrothermal fluids with gypsum. Although white, bassanite has a distinct earthy texture that differentiates it from gypsum. Bassanite will not rehydrate to form gypsum in the presence of water. Hill (1979) reported the unusual occurrence of bassanite in three small caves in southwest Texas. Although originally precipitated on the walls and ceiling as gypsum, high calcium

temperatures (up to 35°C) and low humidity (10% to 60%) resulted in the dehydration of gypsum.

Chemical Properties

Gypsum and anhydrite are able to undergo repeated dehydration and hydration, depending on the depth of burial and availability of water. Gypsum will begin to thermally decompose into the metastable species, calcium sulfate hemihydrate (CaSO₄•1/2H₂O), in heated air above 70°C and at 1 atm of pressure. Differential thermal analysis curves show two endothermic peaks between 100° and 200°C (Deer, Howie, and Zussman 1966). The first peak represents the loss of 1 1/2 molecules of water during the formation of calcium sulfate hemihydrate. Further heating totally dehydrates gypsum forming deadburned (anhydrous) anhydrite (CaSO₄), which is used as a filler in plastics and as a moisture absorbent. The second decomposition peak occurs when the remaining one-half molecule of water is removed. Calcining processes for the manufacture of gypsum wallboard and plasters involve heating gypsum to about 155°C for 1 to 3 hr, during which time calcium sulfate hemihydrate forms.

Heating gypsum liberates water vapor, which helps hinder the spread of fire. Specialized types of wallboard are formulated and manufactured for use as a firestop between multifamily housing, in the lining of elevator shafts, and in the walls and ceilings between living spaces and garages.

Gypsum's solubility in fresh water is approximately 150 times greater than that of limestone. This chemical characteristic provides a source of calcium and sulfur when gypsum is used in agricultural applications. The ionic exchange capability of calcium for sodium prevents the buildup of alkali in soils.

Although gypsum is a very soft mineral, specialized methods of calcining have been developed to manufacture denser, harder crystals. For most uses, the gypsum is ground to a powder and heated in a continuous kettle or batch kettle at 1 atm of pressure. This method of calcining produces anhydrite, rough, splintered crystals known as beta calcium sulfate hemihydrate. This product is used in the manufacture of wallboard and construction plasters. The calcination of pebble- to cobble-sized, high-purity gypsum in an autoclave at elevated pressure produces dense, euhedral crystals of alpha calcium sulfate hemihydrate. This product is used in specialized plasters and cements for art and statuary, architectural applications, industrial prototype modeling, and road and floor repair.

Physical Properties

The softness of gypsum is its most prominent physical feature. It is distinguished by its softness (Mohs hardness of 2) and three distinct cleavage planes. Anhydrite is distinguishable from gypsum

because of its higher specific gravity and greater hardness. When scratched with a piece of copper, gypsum will be gouged, but anhydrite will abrade the copper (a copper residue will be visible on the scratched surface).

Table 4 gives the basic engineering properties of gypsum and anhydrite, and the properties of the evaporates rock salt (halite) and potash for comparison.

ORIGIN AND MODES OF OCCURRENCE

Evaporites are deposits of minerals that formed from the evaporation of seawater or brine. The types and amounts of minerals formed depend on (1) the composition of the source water, (2) the relative solubilities of the dissolved mineral constituents, (3) the climatic conditions and extent of evaporation, and (4) the depth and extent of the depositional basin. Brine may have formed from evaporative concentration of seawater or might have been reconstituted by the dissolution of preexisting rocks (primarily evaporite rocks) by rainwater or groundwater and its subsequent recrystallization in closed basins in an arid climate. Seawater is concentrated by several mechanisms, described here.

The primary depositional environments for evaporites are considered to be either sabkha or subaqueous, with variations related to proximity of terrigenous material and the depth of the basin and seawater. Sabkha evaporites include continental deposits in playa lakes and the more extensive tidal flat deposits. Subaqueous evaporites are formed in either shallow- or deep-water basins. All modern evaporite depositional environments, however, including sabkha deposits, are believed to be of shallow-water origin (Pettijohn 1975). In either case, gypsum and anhydrite are formed from the concentration of dissolved mineral constituents in saline water. Kendall (1981a, 1981b) provides a good overview of each of the depositional facies. Other useful resources for determining depositional environments for gypsum are works by Dean and Schreiber (1978), Kendall (1978), and Raup (1991). There is considerable discussion in geological literature about whether the original mineral deposited is gypsum or anhydrite. Gypsum is metastable, converts to anhydrite at a depth of more than about 600 m, and is readily soluble in groundwater. Two additional environments are salt-dome cap rock and volcanogenic.

Brine Concentration and Evaporite Precipitation

Seawater contains about 3.5% by weight of dissolved solids (Pettijohn 1975). Approximately 78% of the dissolved solids consist of sodium chloride, and calcium sulfate accounts for about 3.6%. If a 1,000-m column of sea water of normal salinity were to evaporate, only 75 cm of gypsum and approximately 13.7 m of halite would be precipitated (Blatt, Middleton, and Murray 1980).

Gypsum will begin to precipitate in an evaporating basin of seawater when the volume has been reduced by evaporation by about 66% and if replenishment and dilution by fresher water do not occur. Halite does not precipitate until approximately 90% of the brine has been evaporated. A natural horizontal and vertical zonation of mineral deposition develops. Calcium carbonate will be precipitated first, followed by gypsum and anhydrite, halite, magnesium sulfate, and potassium salts. Normal seawater is undersaturated with respect to both gypsum and halite. The presence or absence of halite in a thick deposit of gypsum is an indicator of the degree of brine concentration, because considerably more evaporation and brine concentration are required to precipitate halite than gypsum.

Gypsum also forms from diagenetic processes during the dolomitization of carbonate sediments in tidal flat environments. As seawater evaporates to the point at which gypsum begins to

precipitate, the ratio of the activity constants for magnesium ($a_{\text{Mg}^{2+}} = 1.32 \times 10^{-2}$) and calcium ($a_{\text{Ca}^{2+}} = 2.34 \times 10^{-3}$) increases above the normal ratio in seawater of 5.6 (Blatt, Middleton, and Murray 1980). The molar ratio of $\text{Mg}^{2+}/\text{Ca}^{2+}$ also increases from about 5.2 to more than 20. Concentration of seawater by evaporation produces more dense brine that can sink downward through the pores of underlying calcareous sediments. An ion exchange reaction occurs with one magnesium ion replacing one calcium ion. Because the brine has already reached a concentration where gypsum precipitates, the additional calcium released during dolomitization is available to react with any excess sulfate in the brine to form additional gypsum. The chemical reactions that liberate calcium ions and form gypsum from saline brines are as follows:

Sabkha Evaporites

Sabkha is an Arabic term referring to a coastal tidal flat. Numerous geological studies in the 1960 and 1970s examined the formation of gypsum and anhydrite minerals along the Trucial Coast region of the Persian Gulf (e.g., Kinsman 1966, 1969; Butler 1970). These deposits are characterized by a distinctive suite of sediments, including lagoonal limestone, intertidal algal mat limestone and nodular gypsum, and anhydrite-bearing, fine-grained terrigenous or calcareous sediments.

Gypsum and anhydrite form by precipitation of supersaturated brine in the pore space of the tidal-flat sediments. Nodular gypsum and anhydrite are the most common forms, but large poikilitic selenite crystals may also form. Many of the commercially developed gypsum deposits in North America are probably of sabkha origin.

In the tidal-flat sediments a recalcareous, dolomitization occurs during the diagenetic reactions that form gypsum and anhydrite. If terrigenous clastic sediments are present, they are generally chemically unaffected but undergo soft-sediment deformation as the gypsum and anhydrite crystals and nodular masses form. The sabkha environment does not require the presence of a basin for deposition of evaporite minerals, and thick chloride mineral accumulation would not be expected (Schroeder 1970). Depending on the surface water chemistry, laminated gypsum and argillaceous limestone may be deposited in lagoons or ponds on the sabkha surface. The primary difference between carbonate-evaporite and mud-rich sabkhas is the amount of terrigenous sediment deposited on the sabkha surface.

Crystals of gypsum and anhydrite form in several modes in the sabkha environment. The most common mode is the nucleation and displacive growth of crystalline masses in the soft tidal-flat sediments. Soft carbonate or terrigenous clay or silt sediments are pushed aside as nodular masses of gypsum or anhydrite grow. Eventually, the nodules coalesce and the internodular matrix forms a fabric that looks like chickenwire. Laminated or bedded gypsum may be precipitated in shallow, hypersaline ponds, lagoons, or salt pans on the sabkha surface. If the ponds are periodically flooded by fresher water from surface runoff or precipitation, the sediments formed may be argillaceous, micritic limestone.

Carbonate-Evaporite Sabkha

The carbonate-evaporite sabkha environment consists almost entirely of dolomite and gypsum–anhydrite. The most seaward portion of a carbonate-evaporite sabkha environment consists of inner-shelf dolomitic mudstone and pellet wackestone. The dolomitic rock either is massive or has faint, wispy laminae of darker colored, organic-rich clay (subtidal algal mat). Proceeding landward are coarser-grained carbonates such as oolitic or pellet packstone and

grainstone that occur in the intertidal zone. The uppermost sediments (supratidal) include dolomitic mudstone and pellet packstone. Algal mat deposits are present as wispy, black, organic-rich clay. Gypsum intervals up to about 6 m thick are common.

Ancient examples of carbonate-evaporite sabkha gypsum deposits include the Wapsipinicon Formation (Devonian) in southeastern Iowa and the St. Louis Formation (Mississippian) in southwestern Indiana (Jorgensen and Carr 1972).

Mud-Rich Sabkha

In the mud-rich sabkha, most of the tidal-flat sediments consist of clay, silt, and some sand deposited by sheetflood flow from the mouths of wadi channels near the landward margin of the wadi plain (Handford and Fredericks 1980). Marine floodwaters such as storm surges rework the terrigenous sediments to form an extensive, low-slope, tidal-flat surface. Mud-rich sabkha sediments may occur along with carbonate-evaporite sabkha sediments, either interfingering with or prograding across the calcareous tidal-flat surface.

The Mississippian Maccrady Formation of southwestern Virginia and the Jurassic Arapahoe Shale in south-central Utah are ancient examples of mud-rich sabkha environments. Modern-day examples include the coastal mud flats at the mouth of the Colorado River delta at the northern end of the Gulf of California and along the Trucial Coast of the Persian Gulf.

Subaqueous Evaporites

Although most of the commercial gypsum deposits in North America are believed to be of sabkha origin, many thick, widespread, ancient evaporite deposits were deposited by subaqueous processes within enclosed or hypersaline basins. And even though there are several modern-day analogues of sabkha environments, there are no modern-day equivalent depositional environments of subaqueous evaporites.

Three general models of subaqueous evaporites have been developed based on conditions of the depth of the basin and the depth of water: (1) the deep water, deep basin model; (2) the shallow basin, shallow water model; and (3) the deep basin, shallow water model. Each model has one common factor: the presence of a seaward, subaqueous barrier (sill) that restricts the complete circulation of seawater in and out of the basin. High evaporation rates concentrate the trapped seawater and form brine, which is saturated or nearly saturated with respect to gypsum and halite. Crystal precipitation occurs at the air–water interface, and the crystals settle through the water column as a pelagic rain. Variations in the water chemistry from influx of seawater by storm surges, temperature, or evaporation rate form laminations in the rock column. Laminae of sulfate, carbonate, and organic matter 1 to 10 mm thick occur over large areas of the basin. Thin laminations have uniform thicknesses over short distances, and individual laminations have been stratigraphically correlated in wells over distances up to about 100 km.

Ancient subaqueous evaporite deposits include the Castile Formation (Permian) in the United States and the Zechstein Group (Permian) in Europe. The Castile Formation underlies almost 81,000 km² of western Texas, parts of New Mexico, and northern Mexico. The Zechstein Group underlies at least 250,000 km² of northern Europe, including Germany, Poland, and much of the North Sea.

Continental Evaporites

Continental evaporites are similar in origin to mud-rich sabkhas. Mineralization occurs at the surface of playa lakes or within the interstitial pore spaces of soft, terrigenous sediments. Gypsum,

halite, and complex salts of magnesium, potassium, and bromine are deposited in closed basins (no external drainage) in arid environments. Weathering and erosion of rocks in the surrounding higher terrain provide the mineral constituents for the formation of minerals in the playa. Coarser detritus is deposited in alluvial fans at the margins of the playa and surface runoff and groundwater transport the dissolved mineral constituents toward the center of the playa. Mineralization occurs at the surface and within the playa sediments by evaporative pumping and vertical movement by capillary action at the playa surface. Gypsum, with a lower solubility than halite, is deposited within the sediments and also as an efflorescent gypsite crust around the distal margin of the playa. Post-depositional inundation of the playa surface by storm-water runoff and wind erodes and reworks the exposed crusts and underlying soft sediments.

Economic deposits of continental evaporites occur in many parts of the world. The only deposit in the United States commercially used for manufacturing wallboard, however, is the Muddy Creek Formation (Miocene) near Las Vegas, Nevada. The deposit covers about 13 km² and is up to about 30 m thick (Papke 1987). Enormous deposits of playagypsum (gypsite) occur in Australia. Lake Macleod, located near the northwestern coast, covers 2,072 km² and has a gypsite crust about 2 m thick. Lake McDonnell in South Australia covers about 90 km² and has a gypsite crust about 5 m thick; the deposit occupies a former lagoon that was cut off from the sea in post-Pleistocene times. Periodic landward surges of storm water and high tides overflow the barrier and replenish the lagoon with seawater.

Salt-Dome Cap Rock

Gypsum commonly occurs in the near-surface portions of salt domes in the Gulf Coast basin of the United States. Thick layers of the Jurassic-age Louann Salt occur at a depth of about 9 km. Most salt domes are roughly circular in plan view and vary in diameter from 1 km to more than 10 km. Some near-surface domes have a surface expression of elevated topographic relief of about 20 m above the surrounding terrain. Salt domes are diapiric masses of rock salt (halite) that rose upward along fractures or faults by differential lithostatic loading and plastic flow. Salt domes occur in about 100 sedimentary basins worldwide. The Zechstein Salt in northern Europe contains numerous salt domes.

Salt domes contain 5% to 10% water-insoluble material. About 99% of the insoluble impurities in the Louann Salt are anhydrite and a trace amount of calcite (Walker 1974). As a salt dome rises through near-surface, water-bearing sediments, the halite dissolves and a residue, primarily anhydrite, accumulates in the upper portion of the dome. Increased upward vertical pressure occurs during the salt dome's rise and compacts the insoluble residue to form a massive anhydrite rock. As the salt dome rises near the ground surface, groundwater percolation rehydrates the anhydrite to form gypsum.

Salt-dome cap rock forms only minor economic deposits of gypsum in the United States. The gypsum generally contains high levels of soluble salt impurities that are detrimental to the manufacture of wallboard products. Some cap-rock deposits, however, have been developed for portland cement gypsum resources.

Volcanogenic Gypsum

Gypsum sometimes occurs in volcanogenic massive sulfide deposits (VMSDs). Only relatively small economic VMSD gypsum deposits, however, have been developed. The Falkland deposit in southern British Columbia, Canada, is an example. Although relatively small and rarer than any other type of deposits previously dis-

cussed, VMSDs warrant a brief description. They are associated with extensional tectonic settings and submarine depressions such as backarc, mid-ocean spreading centers, and intracontinental rift zones (Ohmoto 1996).

Seawater percolates into the thin crustal rocks and is heated by deep convective circulation in the vicinity of a heat source such as plutonic or upper-mantle rocks. Sulfate mineralization generally occurs during the later stages of hydrothermal activity. In the Kuroko (black ore) metallogenic model, sulfide minerals are deposited by the interaction of hydrothermal fluid (at approximately 350°C) emanating from sea-floor vents with cold seawater. The vents are known as "black smokers" because of the smoke-like appearance of the plume of instantaneously precipitated sulfide minerals. The precipitated minerals accumulate in mound-shaped deposits around the black-smoker vents.

Sulfate mineralization can also occur as a chemical precipitate around the sea-floor vents and as an alteration product of the country rocks. Precipitation of anhydrite is associated with the "black ore" mineral suite (sphalerite + galena + pyrite + barite + anhydrite) that occurs from the interaction of the hot hydrothermal fluids and cold seawater.

Anhydrite and gypsum can also precipitate in the porosity of lower temperature (<150°C) country rocks. Downward percolation of seawater through fractures in lower-temperature country rocks may precipitate disseminated sulfate (SO₄)²⁻ minerals. In the later stages of hydrothermal activity, gypsum and anhydrite may be reduced by Fe²⁺-bearing minerals and organic matter forming hydrogen sulfide (H₂S) that, in turn, leaches additional metals from the country rock.

DISTRIBUTION OF DEPOSITS

Gypsum occurs throughout the world—found to date on every continent except Antarctica (Table 5). More than 90 countries produce gypsum worldwide, and global gypsum resources are enormous. Some known occurrences contain as much gypsum as the total world annual demand. For example, Libya contains more than 80,000 Mt of Jurassic-age gypsum with an estimated purity of 80% underlying an area 65 km long, up to 25 km wide, and locally up to 400 m thick. Latvia contains gypsum resources estimated at 1,000 Mt at a depth of less than 50 m and 14,000 Mt at a depth of greater than 50 m (USBM 1993).

The first gypsum mining in North America occurred in Nova Scotia in 1779. Gypsum was first mined in the United States from Silurian deposits near Syracuse, New York, in 1808. Several gypsum-producing districts have operated continuously since the 1800s. Gypsum was found in the early 1800s during exploration for salt brines in the Mississippian Maccrady Formation in southwestern Virginia. The Plastarco, Virginia, operations of the United States Gypsum Company were worked continuously from as early as 1835. Jurassic-age gypsum has been mined in northwestern Iowa since 1872. The Mississippian-age Michigan Formation has produced gypsum in northeastern Michigan since 1862.

Since the publication of the 6th edition of *Industrial Minerals and Rocks*, some of the oldest gypsum-producing regions of the United States have ceased operations. Notably, the Silurian deposits of western New York and northern Ohio and the Mississippian deposits in Virginia ceased operations after more than 170 years. In most cases, the deposits were not depleted; rather the older, high-cost wallboard manufacturing plants were closed and the manufacturing capacity was replaced by new plants on a viable basis using synthetic gypsum from coal-fired power plants.

Considerable gypsum resources occur in the western part of the United States, Canada, and Mexico. These areas are gener- ally

Table 5. Worldwide distribution of principal gypsum resources

Geologic Age	North America	Europe	Asia	South America	Africa
Holocene	California	NA*	NA	NA	NA

* NA = not applicable (In this case, meaning that there was no occurrence of gypsum during the associated age.)

remote, vary in size from small to very extensive, have complex property ownership issues, and may not be workable year-round because of severe weather conditions. Very often the main factor that would make these deposits valuable is an inexpensive method of transportation of the raw materials or the finished products. Other factors are proximity to market area, work force, utilities, and other parts of infrastructure. Several small operations in the western United States produce portland cement or agricultural gypsum.

United States

Gypsum is currently mined in Arkansas, California, Colorado, Indiana, Iowa, Kansas, Michigan, Nevada, New Mexico, Oklahoma, Texas, Utah, and Wyoming. Outcrops of gypsum in the Arapahoe Shale in Utah and the Chugwater Formation in Wyoming cover hundreds of square kilometers.

In 2003, the top producing states were, in descending order, Oklahoma, Texas, Nevada, Iowa, California, Indiana, and Michigan; they accounted for 73% of the domestic output (USGS 2004).

Calcium sulfate minerals are found within geological strata ranging from the Ordovician through the Holocene. The largest production comes from Mississippian rocks in Atlantic Canada (Nova Scotia, Newfoundland, and New Brunswick), Michigan, Indiana, and, until recently, Virginia. Permian-age rocks are the second largest producer in Texas, Oklahoma, Kansas, Colorado, Wyoming, Nevada, and Arizona. Gypsum is produced from Tertiary-age rocks in California, Jamaica, and Arizona. Gypsum is produced from Jurassic-age rocks in Iowa, Colorado, Utah, and Wyoming.

Texas, Oklahoma, New Mexico, and Kansas contain inexhaustible resources of gypsum, and other chemically precipitated minerals such as salt and potash. The evaporite minerals were deposited in the enormous Permian Basin, which underlies portions of the four states. Two subbasins in west Texas and southeast New Mexico—the western Delaware Basin and the eastern Midland Basin—are separated by the Central Basin Platform. Where extensive hydration of anhydrite has occurred, the resulting purity is high

(>92% purity). Most of the high-quality, value-added products derived from gypsum are manufactured from Permian-age gypsum. The highest purity and whitest gypsum occurs in the Blaine Formation at Medicine Lodge, Kansas, and Southard, Oklahoma, and in the Easley Creek Formation at Blue Rapids, Kansas.

Oklahoma

The primary area of production of high-value-added gypsum products in Oklahoma is in the northwestern part of the state at Southard, Blaine County. In the Anadarko Basin in northwestern Oklahoma, economic gypsum deposits occur within the Shimer, Nescatunga, and Medicine Lodge members of the Blaine Formation in the middle portion of the Beckham evaporite unit. The stratigraphic relationships of the gypsum beds in the Blaine Formation are well exposed in Salt Creek Canyon, just north of Roman Nose State Park, in Blaine County. The Blaine Formation is also a major source of gypsum in southwestern Oklahoma, whereas the Permian-age Cloud Chief Formation contains significant resources in west-central Oklahoma.

The evaporite beds in the Blaine Formation are generally 3 to 9 m thick, and gypsum in the Cloud Chief Formation is up to 30 m thick. Gypsum within the Blaine Formation has a purity of 95% to 99%. Interbeds of shale 0.7 to 9 m thick separate the gypsum intervals. The gypsum beds are typically underlain by thin dolomite beds. Anhydrite thickness increases in the down-dip direction, toward the west, under increasing overburden thickness.

Texas

Gypsum is produced in west-central Texas from the Eskota Member of the Peacock Formation (Permian). Outcrops of gypsum occur along a low topographic escarpment with numerous incised lateral drainages. Hydration and erosion or solution occurs in the down-dip direction, and in lateral drainage courses formed along structural lineaments such as fractures. Several beds of gypsum up to about 6 m thick are interbedded with shale. Overburden consists

of sandy shale. The thickness of the overburden is a significant control on the hydration pattern of the gypsum.

The Castile Formation is an extensive occurrence of gypsum in the Delaware Basin of west Texas and southeastern New Mexico. It is a 440-m section of varved anhydrite and carbonate laminations (laminae 1 to 10 mm thick). Some of the laminae have been traced horizontally for more than 110 km (Anderson et al. 1972). Halite (NaCl) and sylvite (KCl) deposits of the Salado and Rustler formations overlie the Castile Formation.

Nevada

Two companies produce gypsum and anhydrite from the Late Triassic to Jurassic-age Nightingale Sequence of the Auld Lang Syne Group in northern Nevada. The evaporites occur as complexly folded and faulted sequences encased in metasedimentary rocks. A quarryable portion of the deposit is a geologically recent hydration rim extending to a depth of about 40 m. Three wallboard companies operate in the Las Vegas area of southern Nevada. One operation produces gypsite from Miocene-age playa deposits of the Muddy Creek Formation near the plant. The other two companies shifted from using gypsum from nearby quarries to using gypsum imported from northwestern Arizona, almost 160 km away. Papke (1987) published a comprehensive review of Nevada's gypsum resources.

Iowa

The largest concentration of gypsum mining and wallboard manufacturing operations in the United States is in northwestern Iowa, at Fort Dodge in Webster County. Gypsum has been mined continuously in this area since the 1870s. Gypsum occurs in the Jurassic-age Fort Dodge Formation, underlying about 40 km² near the city of Fort Dodge. Although originally deposited in a single evaporite basin, gypsum here occurs as discontinuous masses with a maximum thickness of about 10 m. The gypsum was deposited on an erosional surface that truncated the underlying Pennsylvanian and Mississippian strata. Postdepositional solution and erosion thinned the deposit in many areas, and in some places only remnants of the gypsum exist. The surface of the gypsum has been significantly affected by postdepositional processes. In some areas, the gypsum has been completely eroded by glacial processes.

Pleistocene glacial till covers the gypsum everywhere except where it is exposed in ravines near the Des Moines River. These areas were the first to be mined by underground methods in the late 1800s. In some areas, the gypsum is immediately overlain by the "Soldier Creek beds," an informal stratigraphic unit that protected the gypsum from dissolution and erosion. The Soldier Creek beds consist of calcareous siltstone and sandstone and shale up to 15 m thick that overlie the gypsum (Cody, Anderson, and McKay 1996).

Gypsum also occurs in the Devonian-age Wapsipinicon Formation in southeastern Iowa. USG produces gypsum for portland-cement rock and wallboard at Sperry, in Des Moines County. Gypsum occurs at a depth of about 200 m and has an average thickness of about 3.3 m. The single-level, underground mine began production in 1961 and is currently the deepest gypsum mine in North America. Gypsum is extracted using room-and-pillar techniques and conventional drilling and blasting. The mine underlies an area greater than 3.3 km².

This deposit originally might have been anhydrite. Geological relationships observed in the mine and drilling cores, however, indicate that the deposit has undergone multiple phases of hydration and dehydration. Horizontal bands of anhydrite crosscut upward-thrusted enterolithic folds in the gypsum seam. Maximum hydration is found along the deposit's solution margin and beneath preglacial valleys.

California

The only domestic source of gypsum used for manufacturing wallboard in California is located in Imperial County, the southernmost county of the state. The gypsum occurs in the Miocene-age Fish Creek Gypsum Member of the Split Mountain Group. This deposit, located on the flank of the Fish Creek Mountains, has the largest gypsum production in the United States. The gypsum interval is up to 50 m thick and was deposited on an unconformable surface consisting of granite, fanglomerate deposits derived from the underlying and nearby granitic rocks, arkose, and sandstone. The characteristics and stratigraphic relationships of the gypsum are very similar to the enormous occurrence of gypsum in the Miocene Boleo Formation midway down the Baja Peninsula. The gypsum is unusual in that it has very few impurities; the deposit is devoid of calcium carbonate. The gypsum does, however, contain zones that have been discolored by manganese and iron oxides and zones of bassanite. The bassanite and discolored zones are believed to be related to hydrothermal alteration. The deposit is on the western edge of the Salton Trough, a rift zone with a thin crust and both extensional and right lateral ground movements.

Holocene-age deposits of gypsite at the southern end of the Central Valley have been used as a soil conditioner for many years. These deposits produce gypsite with a purity of 45% to 75% gypsum. Although the purity is too low for use in portland cement or plaster products, the gypsite is useful in treating the alkaline soils of the great agricultural districts of the San Joaquin and Central valleys. A comprehensive review of the gypsum deposits and resources of California was published by Ver Planck (1952).

Indiana

Two companies operate underground gypsum mines in southwestern Indiana. An interval of gypsum 4 to 5 m thick in the Mississippian-age St. Louis Formation occurs at a depth of 100 to 250 m. The variation in depth is caused by the deeply incised surface topography developed in the overlying Pennsylvanian clastic strata. These deposits are good examples of the carbonate-sabkha depositional environment described by Jorgensen and Carr (1972). The St. Louis Formation is about 45 m thick and contains at least 10 discrete carbonate-sabkha depositional cycles. Only the uppermost two cycles, however, contain economic quantities of gypsum. The depositional cycles represent the transgressions and regressions of a very shallow sea over a broad tidal flat in a coastal sabkha environment.

The beds dip westward into the Illinois Basin about 6.6 m/km. The updip edge of the gypsum is exposed to subsurface groundwater activity and is actively undergoing solution. Groundwater percolating through the overlying strata and down dip from the Mitchell Karst Plain has formed an extensive cavity system of hydrogen-sulfide-bearing, water-filled fractures and caves. One of the mines has been flooded twice during its almost 50 years of operation. The first flood occurred when a development entry encountered the cavity system during blasting. The second occurred when groundwater continued to dissolve gypsum and worked around the engineered bulkhead constructed after the first flood. Careful evaluation of diamond core drilling information, mine planning, and ongoing underground examination assist in keeping active mining areas away from potential solution zones.

Michigan

Gypsum is produced in the eastern part of the Michigan Basin near the western shore of Lake Huron. Since the publication of the 6th edition of *Industrial Minerals and Rocks*, the underground mining operations in the Grand Rapids area have ceased. The deposits here are in the Michigan Formation of Mississippian age, and consist

of multiple units of gypsum from 1.5 to 13 m thick, separated by beds of shale varying from a fraction of a meter to 15 m thick. Overburden is glacial till ranging in thickness from 13 to 25 m. Three companies operate in the Alabaster–National City area: USG, National Gypsum Company, and Michigan Gypsum. These companies supply gypsum to wallboard plants in Detroit, Michigan, and Waukegan, Illinois, and cement plants in situ ated on or near Lake Michigan, Lake Huron, and Lake Erie.

Colorado

Extensive resources of Permian-age gypsum up to about 27 m thick occur near the town of Gypsum in Eagle County, west-central Colorado. One quarrying and wallboard manufacturing operation is located in the area. Gypsum also occurs in the Great Plains near the town of La Junta in southeastern Colorado.

Kansas

Gypsum occurs in Lower Permian rocks in central Kansas. The Georgia–Pacific operation extracts gypsum from Easley Creek Shale Formation in the upper part of the Council Grove Group. The National Gypsum Company quarries gypsum from the Medicine Lodge Member of the Blaine Formation in south-central Kansas, which corresponds to the lowermost gypsum strata that occur in the USG operations in northwestern Oklahoma.

New Mexico

Although considerable Permian calcium sulfate occurs in the Permian Basin deposits in southeastern New Mexico, none is currently being mined. There are, however, three operating quarries in the north-central part of the state that are producing gypsum from the Todilto Formation of Jurassic age.

Utah

Gypsum has been produced for many years from the Jurassic-age Arapien Shale in south-central Utah. Several stratigraphic intervals of gypsum are interbedded with shale and mudstone and have been complexly folded into a series of anticlinal and synclinal folds. The Arapien Shale outcrops in the foothills along the western slope of the southern extent of the Wasatch Mountains. The gypsum is more resistant to erosion than the clastic rocks and occurs as ridges. The Arapien Shale is also exposed on the western flank of the San Rafael Swell in southern Utah. The San Rafael Swell is an asymmetric structural dome and several beds of gypsum are exposed over more than 100 km².

Wyoming

Two companies produce gypsum in northwestern Wyoming. Large resources of gypsum are located southeast of Greybull in north-central Wyoming. A gypsum interval up to 22 m thick occurs near the top of the Chugwater Formation (Triassic). The gypsum is interbedded with shale.

Canada

The majority of gypsum produced in Canada comes from Nova Scotia. Several companies produce gypsum and various blends of gypsum and anhydrite from the Mississippian-age Windsor Group. The majority of the material produced is exported to gypsum wallboard and Portland cement customers along the Atlantic and Gulf coast regions. Several companies operate large quarries in Nova Scotia. The National Gypsum Canada Ltd. quarry at Milford, near Halifax, is the largest gypsum quarry in the world. Adams (1991) published a comprehensive review of gypsum deposits and occurrences in Nova Scotia.

Gypsum is also produced in other provinces, including Newfoundland, New Brunswick, Ontario, Manitoba, Alberta, and British Columbia.

Atlantic Canada

The major deposits of gypsum in Nova Scotia occur in the Mississippian Windsor Group, consisting of up to 760 m of interbedded marine evaporites and nonmarine sediments that were deposited in a large, complex intracontinental basin. Traditionally, the Windsor Group has been subdivided into five subzones, named “A” through “E” in ascending order. Giles (1981) reinterpreted the depositional history of the Windsor Group and identified five major transgressive–regressive depositional cycles. The cycles correlate with the earlier subzone nomenclature. Each cycle is characterized by one or more transgressive–regressive cycles. Economic gypsum and anhydrite deposits occur in the two lowest cycles. The earliest cycle (the A Subzone) represents a single rapid marine invasion followed by a slow regression of the sea. The A Subzone consists of up to 305 m of anhydrite with a variable thickness of gypsum near the surface. The depth of hydration varies from 0 to 76 m. The B Subzone also represents extensive evaporite deposition but consists of numerous transgressive–regressive sequences, all similar but on a much smaller scale than found in the A Subzone. The B Subzone consists of about 400 m of gypsum interbedded with dolomite, limestone, and siltstone. Gypsum occurs at a depth of up to 100 m.

The gypsum and interbedded waste units have been complexly folded and faulted into a series of anticlines and synclines. The folding is complex and varies from upright to recumbent. The folds have been refolded and truncated by normal and reverse faults.

Ontario

Only one company mines natural gypsum in Ontario: Canadian Gypsum Company, Ltd. A subsidiary of USG, it operates an underground mine in the Upper Silurian–age Salina Group near Hagersville, about 100 km southwest of Toronto. The gypsum seam is about 1.1 m thick, and the room-and-pillar mine is situated at a shallow depth (30 to 40 m) beneath the surface. The gypsum is overlain by 3 to 13 m of thinly bedded shale and dolomite and up to 15 m of glacial till. The gypsum has an average purity of about 85% and is beneficiated by heavy-media separation. The G-P Gypsum Corporation also operates a wallboard plant at Caledonia, near the Canadian Gypsum Company operation. Although natural gypsum was used for many years, production from the Caledonia mine has ceased and synthetic gypsum is currently used. The gypsum seam is 2.5 to 3 m thick and is located stratigraphically about 70 m below the Hagersville seam. The inactive and flooded Drumbo mine, formerly operated by Westroc Industries Ltd. (now a part of BPB North America), is about 75 km northwest of the Hagersville area. The Drumbo mine was active from about 1978 until 1993. The gypsum mining seam averages 1.8 m thick and is located 120 m below the surface.

Western Canada

Gypsum is produced in the provinces of Alberta, British Columbia, and Manitoba for wallboard-manufacturing plants in Edmonton, Vancouver, and Winnipeg. The quarries are far from the wallboard plants. The deposits in British Columbia are on the western flanks of the Canadian Rocky Mountains in environmentally sensitive areas. The VMSD at Falkland, near Kamloops, is quarried for Portland cement rock.

Mexico

Mexico has tremendous resources of high-quality gypsum located in many parts of the country. Although Mexico is the second-largest

exporter of gypsum to the United States for the manufacture of wallboard, it has only three wallboard plants in the country. The gypsum industry continues to grow in Mexico as more development occurs in the commercial and institutional sectors. The primary use for gypsum in Mexico is in manufacturing portland cement rock and building plasters. Gypsum wallboard is rarely used in residential construction. A smaller but growing market is industrial plasters used in the manufacture of ceramics (cups and plates) and sanitary ware (sinks and toilets). Numerous *yaseras* throughout the country supply the construction plaster needs of local markets.

Baja California del Sur

In this area, the gypsum occurs in the Miocene Boleo Formation, a marine-clastic sequence that is also the host for copper, zinc, and cobalt mineralization. Gypsum in the Boleo Formation shares similarities with the Miocene Fish Creek Gypsum in California. Up to 110 m of gypsum was deposited on an irregular bedrock surface consisting of andesitic igneous rocks of the Comondu Formation. The gypsum is overlain by marine limestone.

Puebla State

Deposits of Miocene–Pliocene gypsum occur to the southeast of Mexico City in the southern part of Puebla State. Several thick gypsum beds outcrop near the village of Izucar de Matamoros extending eastward to the village of Axochiapan. The deposits supply portland cement rock to numerous plants in the Mexico City–Puebla metropolitan areas. Gypsum from this region has also supplied the first wallboard plant in Mexico, located in Puebla, for more than 30 years, and numerous small plaster-calcining plants.

Nuevo Leon and Coahuila States

The cities of Monterrey and Saltillo, located in Nuevo Leon and Coahuila states, respectively, are areas of tremendous growth in northern Mexico. These cities are only a few hours south of the United States. There are several portland cement plants located in this region, and Monterrey is the center for the sanitary ware and ceramic industry in Mexico. Of the three gypsum wallboard plants in Mexico, two are located just north of the city of Monterrey.

Gypsum deposits in northern Mexico occur in the Cupido Formation (Cretaceous) and Minas Viejas Formation (Upper Jurassic). Near Monterrey, gypsum in the Minas Viejas Formation commonly occurs in the breached cores of complex anticlinal structures of the Coahuila Marginal Fold Belt, such as Portrero Grande and Sierra del Fraile. These structures are diapiric structures of rock salt that have pushed upward through Upper Jurassic and Lower Cretaceous strata. An oil well drilled in the Sierra de Minas Viejas fold/diapir structure penetrated approximately 4,000 m of evaporites (Weidie and Martinez 1970). Gypsum occurs as a capping of the rock salt in some of the large fold structures. The gypsum is often contaminated by fragments of rock salt, however, and generally is not used for wallboard manufacturing.

Gypsum of the Cupido Formation is widespread in northern Mexico. The gypsum occurs along the flanks of limestone ridges in Nuevo Leon and Coahuila states. Two unusual occurrences of gypsum outcrop between Monterrey and Monclova. The diapiric masses of Minas Viejas gypsum, elliptical in shape with a major axis up to 1.5 km long, have pushed through the upper crust an estimated distance of about 5 km. The gypsum contains inclusions of igneous rock plucked from the walls of the conduits during its upward migration.

Other Resources in Mexico

There are significant occurrences in other parts of Mexico, including Chihuahua, Colima, Oaxaca, San Luis Potosi, Sonora, and other

states. The most recently developed gypsum deposits are located in Colima in southwestern Mexico. Gypsum outcrops in a mountainous area covering almost 60 km between the villages of Coquitmatlan and Ixtlahucan. The developed gypsum deposits are located near the main transportation artery (*autopista*) between Guadalajara and the Port of Manzanillo. Quarried gypsum is transported about 70 km to a state-of-the-art, multiple-use, rock-loading facility in the Port of Manzanillo for shipment to the Pacific Northwest.

TECHNOLOGY

Exploration Techniques

Several direct and indirect methods exist for determining the presence of gypsum. Because gypsum has been used as a building material and artist's medium for several thousand years, much is known about the worldwide distribution of deposits.

The initial step in exploring for gypsum is a thorough literature search. The U.S. Geological Survey (USGS) published thorough reviews of the gypsum deposits of the United States in 1904 and 1920 (Adams 1904; Stone et al. 1920) and a comprehensive bibliography on gypsum and anhydrite in 1960. Dean and Johnson (1989) compiled a survey of anhydrite and gypsum deposits. Sources of information in North America include numerous state and provincial geological surveys and federal agencies such as USGS, the Instituto Nacional de Estadística Geográfica e Informática (INEGI) in Mexico, and the Geological Survey of Canada. Information on foreign resources may be obtained from similar organizations or international organizations such as the United Nations. Other sources of information include unpublished university theses and dissertations and records of water or oil and gas wells. For example, the initial discovery of two large deposits of gypsum in Iowa and Indiana came from water-well records that are required to be submitted to the state geological survey.

The potential for the existence of evaporite minerals can be determined by studying the stratigraphy in regions where sedimentary rocks occur. In North America, most of the significant deposits of gypsum occur in rocks of Silurian, Devonian, Mississippian, Permian, Jurassic, and Miocene age. If shallow evaporite rocks are believed to be present, then further information may be derived by examining outcrops and topographic maps. Deeper deposits can be initially investigated by examining geophysical logs, oil and gas lithologic strip logs, or water-well information. Many state agencies require samples of cuttings or of diamond drill cores for retention in a permanent repository. As the stratigraphic and lithologic details of a target area are developed, the structural conditions should also be ascertained. Primary, regional structural features such as folds and faults expose gypsum-bearing strata or are pathways for the hydration of deeper anhydrite strata. Linear structural features such as joints and fractures also determine the minability of a gypsum deposit.

Gypsum has some unique features that are directly visible or interpreted from the topography or hydrology of an area. For example, outcrops of gypsum are rare in humid environments because of the relatively high solubility in the presence of surface water or groundwater. Although gypsum is important in agriculture as a soil amendment, outcrops of gypsum support only sparse vegetation.

Stratigraphy

Gypsum and anhydrite are usually associated with common sedimentary rocks such as shale and dolomite. It is more commonly associated with dolomite than limestone because the formation of gypsum is often associated with dolomitization of micritic tidal-flat sediments. Megascopic fossils are almost universally absent in gypsum and anhydrite deposits because of the high salinity of the water in which the evaporites were deposited (Pettijohn 1975). The

physiochemical characteristics of gypsum generally rule out its preservation in igneous or metamorphic rocks, except for minor occurrences associated with hydrothermal fluids. A significant exception is the gypsum that occurs interbedded with marble and tremolite schist in Riverside County, California. The country rocks encasing several thick beds of gypsum and anhydrite were subjected to regional metamorphism. The uppermost portion of the evaporite seams was hydrated to form gypsum, but anhydrite occurs at depth. Underground mining to a depth of about 35 m was carried out from the 1920s to 1946.

Topography

The high solubility of gypsum results in areas of low topographic relief or highly dissected terrain in humid regions. For example, the gypsum-bearing portion of the Mississippian Maccrady Formation crops out for about 30 km along the footwall of the Saltville Thrust Fault in southwestern Virginia. Tectonically thickened portions of the Maccrady Formation occur as a prominent valley between more competent ridges of sandstone (Pice Formation) and dolomite (Honaker Dolomite) in the thrust fault hanging wall. The Mississippian Windsor Group in Nova Scotia consists of about 800 m of gypsum and anhydrite interbedded with limestone, siltstone, and sandstone. Pinnacles of gypsum and anhydrite occur with deep pockets and sinkholes filled with clay and organic material.

Quarryable gypsum occurs as a product of the near-surface hydration of anhydrite by groundwater. The deposits of Kansas, New Mexico, Oklahoma, and Texas occur in semiarid regions. The pattern and degree of hydration of anhydrite to gypsum are a function of: (1) stream drainage patterns; (2) type and thickness of overburden; and (3) structural features such as fractures, joints, and faults. Gypsum typically caps low escarpments in the semiarid environments. In the outcrop area, some of the gypsum has been dissolved and eroded, resulting in locally poor quarrying recovery. Headward erosion of gypsum along structural discontinuities aids in the transmission of groundwater to hydrate anhydrite in the downdip direction, but may also result in poor quality or recovery near the streams. In the downdip direction, the gypsum is overlain by an increasing thickness of overburden, generally consisting of sand, shale, siltstone, or limestone. The type of overburden and its permeability affect the degree of hydration of the underlying seam.

In arid regions, gypsum outcrops are often more resistant than commonly associated beds of mudstone or shale. The Jurassic Arapahoe Shale in south-central Utah consists of several gypsum intervals that have been complexly folded. The gypsum outcrops as hogback ridges with slopes of mudstone or shale. The Miocene Fish Creek Gypsum Member of the Split Mountain Group in Southern California is well exposed as barren hills along the limb of a syncline and is underlain by conglomerate and igneous rocks.

Vegetation

Although gypsum provides many benefits in agricultural applications, outcrops of gypsum are relatively hostile to the growth of vegetation. The development of karst topography on gypsum outcrops in humid regions such as in Nova Scotia supports vegetation primarily because of the accumulation of organic material in pockets of clay.

In arid regions of the western United States, outcroppings of gypsum are largely barren or only sparsely covered by vegetation. The uppermost part of the outcropping consists of soft, friable, secondary gypsum (gypsite) derived by the evaporation of capillary water from the underlying rocks. The surface often has the appearance of a wrinkled orange and is called "cryptogamic crust." The crust, consisting of gypsite, cyanobacteria, lichens, fungi, or mosses, forms when moisture is available.

A distinctive change in the density or type of vegetation often distinguishes gypsum from limestone in interbedded and folded sequences. Juniper shrubs (a conifer) commonly grow sparsely on gypsum outcrops, but grow more abundantly on limestone. Saguaro cactus thrives on some gypsum deposits in southwestern Mexico. In Colima, for example, the upslope contact of gypsum with limestone on steep, colluvium-covered slopes is generally defined at the highest occurrence of saguaro cacti. Beds of clay impurities within a gypsum deposit may support more vegetation, such as creosote bush.

Hydrology

Examining maps may provide a hint about the presence of gypsum. Sulfate-laden groundwater discharging from springs or in streams is often noted as "sweetwater" or *agua dulce*. For example, gypsum has been mined at Sweetwater, Texas, for almost 100 years. Sweetwater Creek flows across the outcrop area of the Permian-age Blaine Group. The high solubility of gypsum also forms karst terrain, with little to no surface drainage in some regions.

Deposit Evaluation

Drilling and Sampling

The primary method of evaluating a gypsum deposit is by diamond core drilling. Drilling is rarely done, however, on a regular sized or shaped grid. Rather, drill holes are best placed to answer basic or specific questions about the deposit regarding (1) its thickness and lateral extent; (2) the presence, type, and distribution of impurities; and (3) other factors that may affect minability or quality, such as solution zones, erosional cutouts, or an irregular bedrock surface.

The drilling campaigns to initially outline a gypsum deposit are not sufficient for the long-term planning and operation of a mine or quarry. Subsequent programs provide infill drilling information and answer localized questions.

The diamond drill core is generally sampled by splitting the core longitudinally, preserving one half and preparing the other half for quality analyses. The sampling interval is typically 1.5 to 2 m. The core is crushed in a laboratory crusher and ground in a pulverizing mill to about 100 mesh. The testing methods for the chemical analysis of gypsum are defined in ASTM C471M-01.

Testing Procedures

In general, testing gypsum rock for wallboard manufacture involves determining the amount of chemically combined water and soluble salts. The purity of the sample is determined by measuring the loss of weight after heating for a specific period of time and temperature range. Absorbed moisture (free moisture), however, must be removed first by drying the sample to prevent overestimating purity. Overheating the sample can also cause thermal decomposition of impurities such as carbonates and some clays, and can result in an overestimate of purity.

Free-moisture and combined-moisture losses may be measured by weighing samples with laboratory balances before and after heating in ovens. Computerized systems are also available that perform the drying, calcining, and weighing functions using only one analytical instrument.

Soluble salts are leached from the pulverized samples for determining the content of total dissolved solids (TDS) with an electrical conductivity meter and chloride ions with an ion-specific probe.

Whiteness and brightness are important in manufacturing and marketing industrial and ceramic plasters. Although the color of the calcined plaster may not affect the quality of the finished product, it may have an effect on competitive advantage in the marketplace.

Food- and pharmaceutical-grade gypsum is analyzed for the presence of heavy metals, such as lead, arsenic, and selenium, as well as for the presence, type, and amount of bacteria.

Mining

Most of the world's gypsum is produced by surface-mining operations. In North America, only five active underground gypsum mines were in operation in 2004. Two are located in Indiana, and one each in Iowa, Michigan, and Ontario, Canada. Four additional North American underground gypsum mines ceased operations early in the 21st century after extensive periods of operation. Gypsum was mined in southwestern Virginia from about 1830 until 2000—a period of about 170 years. Several long-term, underground mining operations in New York, Kansas, and Ontario ceased operations in the early part of the 21st century.

Quarrying

Gypsum is extracted from near-surface deposits by quarrying methods. Overburden consisting of glacial materials (till, sand, clay), shale, mudstone, siltstone, sandstone, sand and gravel, or limestone, is removed from the gypsum by various stripping methods. Stripping is performed by scraper, truck and excavator, front-end loader or hydraulic excavator and truck, dragline, and bulldozer. The maximum economic stripping limit (thickness) is about 30 m and depends on the method of stripping and the thickness of the underlying recoverable gypsum.

Final cleanup of the stripped gypsum surface is important, and is determined by the final products to be manufactured. If the quarried rock is to be used as agricultural products, Portland cement rock, or wallboard, then much of the impurities can be removed in the finer fractions during crushing and screening. Conversely, gypsum used for high-quality, high-value-added products requires more stringent cleaning. For example, articulated hydraulic excavators with multiple, interchangeable bucket widths scrape clay from the gypsum surface and fractures that extend deep into the gypsum.

Drilling and blasting is the primary method of quarrying gypsum. Quarry benches are generally about 8 m in height. Hydraulic rotary drilling and auger drilling are commonly used. Gypsum is soft and penetration rates up to 7 m/min are possible. Blast holes are generally 50 to 100 mm in diameter and spaced relatively close together to distribute the explosive forces throughout the rock mass. The blasting components used include ammonium nitrate and fuel oil (ANFO) blasting agent, cast boosters, nonelectric blast initiation systems. Bagged emulsion is used in wet holes. About 1 kg of blasting agents per ton of broken gypsum is an average tonnage factor. The elastic nature of gypsum, the presence of solution-enlarged fractures, and the possible presence of water contribute to poor and inefficient rock fragmentation. An incorrectly designed blasting pattern may result in irregular fragmentation, including excessive oversized rock requiring secondary breakage, excessive fines, or irregular floor conditions that are detrimental to the efficiency and maintenance of mobile equipment. Quarry haulage trucks or over-the-road dump trucks transport the quarry-run broken gypsum from the quarry site to the primary crusher.

Another method of extracting gypsum from quarries that is gaining acceptance is the use of a surface miner. This is an adaptation of highway-resurfacing technology in which a horizontally rotating mandrel with cutting teeth chips a way at the asphalt and either discharges the broken material in a windrow or directly into a haulage truck. Specialized machinery using this technology is being developed to quarry coal, gypsum, and limestone. The size, spacing, and arrangement of the cutting teeth on the mandrel are

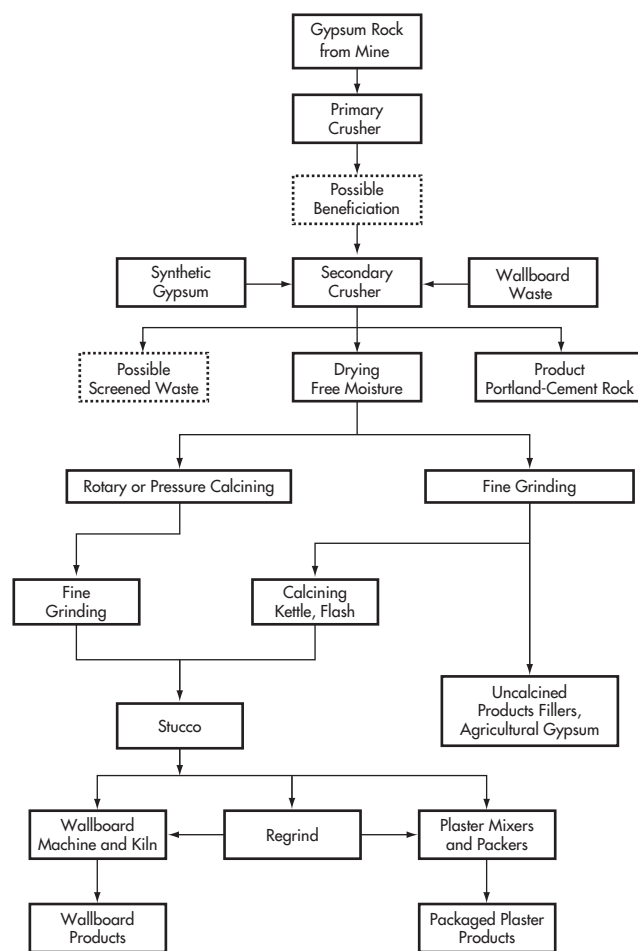

Figure 1. A general flow diagram of the manufacture of gypsum wallboard

important factors in the efficient production of gypsum rock. Advantages over standard quarrying techniques are the following:

- Elimination of drilling and blasting
- Elimination of primary crushing
- Direct removal of interbedded thin waste beds or low-purity zones
- Increase in recovered gypsum purity by removal of off-specification material from windrows
- Maximization of the overall recovery of the gypsum near structures or utilities

Underground Mining

Underground mining of gypsum is far less common than quarrying. There are currently only five active underground gypsum mines in North America. The mines are located at a depth of < 30 m (Hagersville, Ontario, Canada) to about 200 m (Iowa and Indiana). Access to the mine workings for workers, supplies, ventilation and escape, and production is by either vertical shafts or inclined adits (tunnels). The mined interval varies from 1.1 m (Hagersville) to 3.7 m (Iowa, Michigan, and Indiana).

Gypsum is extracted using the room-and-pillar method, in which pillars are left in place to support the roof strata and the

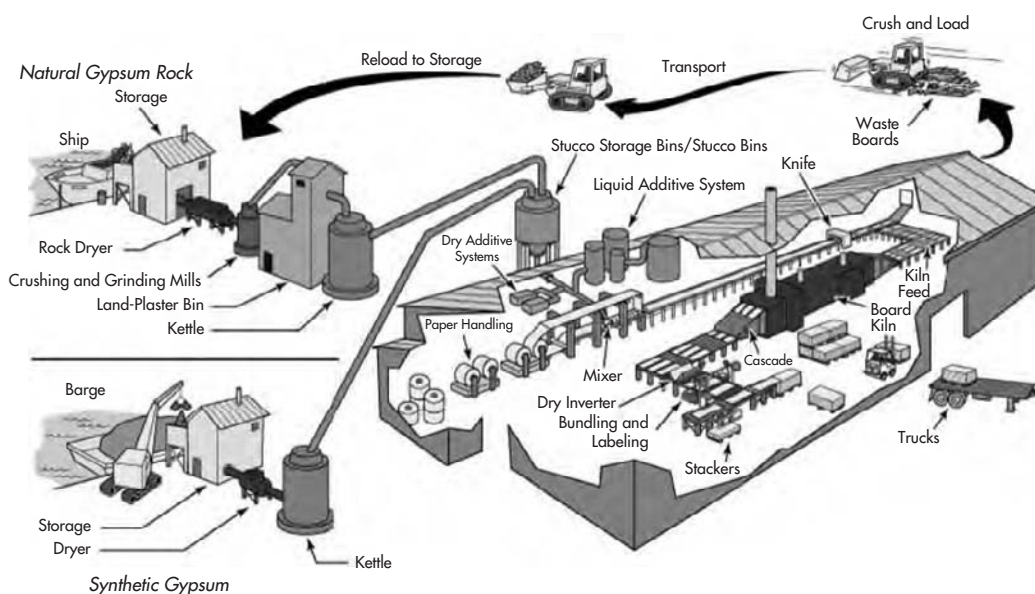

Figure 2. A conceptualized drawing of the manufacture of gypsum wallboard

gypsum is removed in a checkerboard pattern. The extraction ratio, which is the proportion of material mined to material left in the supporting pillars, varies from 65% to 80%.

Drilling and blasting of gypsum in underground mines is similar to methods used in gypsum quarries. The blast-hole pattern, however, is drilled horizontally into the advancing face of a mine heading. The number of drill holes, orientation, depth, and sequence of blasting are designed to maximize breakage of the gypsum and to maintain the integrity of the adjacent pillars and immediate mine-roof strata. The roof strata are reinforced by roof-control fixtures, generally epoxy resin-grouted bolts, up to 1.5 m long. The resin-grouted bolts bind the roof strata together to form an integral beam that is stronger than the individual strata.

Underground gypsum mines are generally very stable. Long-term measurements of roof and pillar convergence (vertical closure) at the USG mine at Sperry, Iowa, indicate that the structure should be stable for hundreds of years. An underground gypsum mine near Grand Rapids, Michigan, is currently being used as a computer network security center.

Processing

Wallboard Manufacture

Figure 1 is a general flow diagram for the manufacture of gypsum wallboard, and Figure 2 is a conceptualized drawing of that process. Three possible sources of raw material are shown: (1) natural gypsum rock delivered from an on-site quarry or underground mine, (2) synthetic gypsum delivered from a nearby power plant or by barge, and (3) off-specification wallboard recycled into the manufacturing stream.

Quality Assurance and Quality Control Issues

No single statement can be made about the effects of the presence of impurities in gypsum deposits. The manufacturing processes for wallboard can be adjusted for a wide range of gypsum purity. Wallboard can be made from relatively low-purity (low 80s) or very-high-purity (high 90s) gypsum. The key is that the purity of the gypsum supplied from the mine or quarry, as well as the calcined

gypsum stucco, should be consistent. Formulating calcined stucco with air-entraining agents can decrease the weight of the finished wallboard, enhancing its purity.

Most gypsum contains 10% to 15% impurities, although some deposits may be exceptionally pure (i.e., +95%) or somewhat impure (i.e., 80%). In general, the amount of impurity that can be tolerated depends on (1) the type of impurity, (2) the product being manufactured, and (3) the competitive situation.

Impurities are usually separated into three categories, based on their effect on the manufacturing process and finished products:

1. Insoluble or relatively insoluble minerals such as limestone, dolomite, anhydrite, anhydrous clay, silica minerals
2. Soluble evaporite minerals, including chlorides (halite, sylvite, etc.) and sulfates (mirabilite, epsomite, etc.)
3. Hydrated but insoluble minerals (e.g., the montmorillonite group of clays)

Insoluble Impurities

Insoluble impurities, especially carbonates, reduce the strength of the rehydrated stucco and increase the weight of the finished plaster or wallboard products. A greater amount of lower-purity stucco is required to obtain a specific strength plaster or wallboard. Wallboard products that are heavier increase both the transportation costs of the finished products and the difficulty of installation. These minerals can also occasionally act as hydration accelerators. Many commercial gypsum deposits contain as much as 10% to 15% insoluble impurities.

Chert is present only in trace amounts in some deposits and does not significantly affect the manufacturing of wallboard. Chert in the feedstock to the calcining mill can result in excessive abrasive wear of grinding equipment.

Dolomite is detrimental in industrial plaster used in the manufacture of sanitary ware such as sinks and toilets or ceramic products such as dishes. It has a higher specific gravity than gypsum and sinks in the stucco slurry, forming projections at the mold-cast interface and surface pits in the cast product.

Soluble Evaporite Impurities

Soluble evaporite impurities affect calcining temperature, fluidity of the stucco slurry, setting or rehydration time, and bonding of paper and core in wallboard. These minerals are usually limited to no more than 0.02 % to 0.03% by weight of the gypsum rock and strongly affect vapor pressure, which in turn affects the gypsum hydration–dehydration reactions.

Hydrous, Insoluble Impurities

The principal effect of hydrous, insoluble impurities is in the absorption of moisture in the finished product and on bonding characteristics of the rehydrated stucco core of wallboard to its paper covering. Hydrous clays up to 1.0% to 2.0% may be tolerated.

USES

Gypsum is a very versatile mineral that can be used in the manufacture of several hundred products. Processing methods vary from simply crushing and sizing of quarry-run gypsum to specialized methods of calcination in closed pressure vessels.

Uncalcined Gypsum

Gypsum that has been processed only by grinding and sizing is known as land plaster, portland cement retarder, and Terra Alba. Land plaster is used for agricultural gypsum and a raw feedstock for manufacturing wallboard and plasters. Portland cement retarder is used in the manufacture of portland cement. Terra Alba is used in food and pharmaceutical applications.

Uncalcined gypsum is principally used as a retarder for portland cement, soil conditioner, mineral filler, and in other minor industrial applications. About 25% of the gypsum mined in the United States is used in these markets. In countries where building practices differ from those in the United States and Canada (poured concrete, block, or brick), however, the relative usage of gypsum varies widely.

Although calcium sulfate deposits are the world's largest sulfur resources, only minor quantities of gypsum and anhydrite have been used to produce sulfur or sulfur compounds. This use is accompanied by a unique, site-specific set of economics, because sulfur is generally available from nongypsum sources at lower cost.

Agricultural Gypsum

Gypsum provides several benefits in agriculture. The specifications of agricultural gypsum are primarily related to the degree of fineness (particle size and surface area). As gypsum dissolves, it is a source of elemental calcium (25% by weight) and sulfur (20% by weight). Gypsum has a neutral pH (7.0) and is 150 times more soluble than ground limestone. Finely ground agricultural gypsum permits rapid dissolution and absorption by plants. Long-term availability of these elements during a growing season can be accomplished by applying agricultural gypsum of multiple particle sizes. Finely ground gypsum (100% passing through a 425-mesh screen) can also be dissolved in irrigation water for easy application.

Gypsum loosens and aerates heavy clay and wet soils. The acidity of aluminum-rich lateritic soils is buffered by gypsum. The gypsum particles act as nuclei for the flocculation of clay particles, producing more granular and well-drained soils. Cation replacement of calcium for sodium reduces the alkalinity of soil. Gypsum also combines with potassium-aluminum silicates in soil, releasing potassium as a nutrient. Applying gypsum prevents the formation of a crust in the soil where low electrolyte irrigation water is used or where the soil has a high sodium content. The soil crust contributes to excessive runoff and erosion in sloping terrain or pooling of water on more level ground.

In dairy-farm applications, gypsum can be applied to manure piles to prevent the loss of nitrogen by reacting with nitrogen to produce ammonium sulfate. An additional benefit is reduced ammonia odors.

Gypsum can be applied to bodies of water with high total suspended solids, such as muddy ponds, where it acts as a flocculating agent to settle the suspended clay particles.

Portland Cement Rock

Gypsum, anhydrite, or a mixture of gypsum and anhydrite is used in the manufacture of portland cement. Gypsum and anhydrite are used as a source of SO₃. Adding calcium sulfate also controls the early-strength characteristics of cement and product shrinkage during drying and curing. About 3 to 5 wt % of calcium sulfate compounds are ground with clinker to form portland cement.

Gypsum also aids in the grinding of clinker by reducing the tendency of fine particles to agglomerate and adhere to the walls of the mill and grinding media (Hansen et al. 1988). Gypsum is much softer than clinker, is easier to grind, and has a much greater fineness (surface area) than clinker. Portland cement rock is typically ground to a particle size of 6 to 65 mm. Calcium silicates and aluminates that constitute clinker have negatively charged oxygen ions on the crystal surfaces. The hydrogen ions in the water molecules of the gypsum particles bind to the negatively charged clinker particles. The neutralization of the electrical charges by the attraction of the gypsum to clinker particles reduces the tendency for agglomeration.

Terra Alba

Terra Alba is white, high-purity, uncalcined gypsum that has numerous uses in the food and pharmaceutical industries. It is made by fine grinding and air separation of gypsum with a purity of greater than 97%. Terra Alba has a minimum calcium content of 23% (by weight).

Beer Brewing

This type of gypsum supplies calcium ions to buffer the pH and reduce the hardness of water used in the beer-brewing industry. The yield of the main mash is increased by promoting the proper gelatinization of the starch in the cooker mash, as well as protein degradation and starch conversion. Flocculation and precipitation of undesirable protein complexes is achieved by adding Terra Alba. These effects produce beer with improved stability and shelf life.

Baking

In the baking industry, Terra Alba is used as a source of supplemental calcium. It is used in enriched flour and breads, pasta products, baking powder, yeast foods, and bread conditioners. Calcium enrichment of bakery products, in addition to providing supplemental calcium, also counteracts the effects of excess phosphorous in a person's diet. Many foods are high in phosphorous, but few foods are good sources of calcium. A deficiency of calcium makes the dough soft and sticky.

Pharmaceuticals

Terra Alba is used as a diluent and inert extender in pharmaceutical products such as aspirin tablets. It also provides a source of dietary calcium.

Other Food Applications

Terra Alba is also used in canned vegetables, cheeses, and artificially sweetened jellies and preserves.

Glass Batch

Relatively pure uncalcined gypsum, depending on glass-batch chemistry, can also substitute for salt cake (sodium sulfate) in glass manufacturing.

Oxidizing Agent

Thermal decomposition of gypsum in the glass melt produces sulfur dioxide as well as oxygen. The oxygen reacts with any free or reduced sulfur to form additional SO_2 . Increasing the amount of gypsum in the glass batch decreases the sulfur content in the melt and results in a lighter-colored glass. Iron pyrites and carbon or blast-furnace slag are commonly added to the melt to manufacture amber-colored glass. Green-colored glass has a natural amber hue.

Fining Agent

Adding gypsum provides a source of sulfate in soda-lime glass. Decomposition of gypsum produces sulfur dioxide, which, in low concentrations, removes seeds and forms a clear glass.

Removal of Surface Scum

Surface scum can form on molten glass because of improper flow conditions in the furnace, especially near the bridgewall. The presence of coarse sand and stratification of the raw materials in the batch may result in selective melting and the formation of a surface scum. Gypsum added to the glass melt reacts with sodium carbonate to form sodium sulfate. The sodium sulfate melts and reacts with free silica to form sodium silicate, which in turn separates from the molten glass and floats on the surface.

Calcined Gypsum

Gypsum chemically transformed by heat or pressure to remove three fourths of the water of crystallization is known as calcium sulfate hemihydrate, stucco, and plaster of paris. Different methods of calcination produce two products, beta hemihydrate and alpha hemihydrate, depending on the processing method used. The chemical reaction, however, is the same for both products and is reversible at atmospheric temperatures and pressures:

Many different products may be manufactured from alpha or beta hemihydrate or a mixture of both. The products are further mixed with portland cement, fiberglass, plastic resins, and other materials to produce products with high strength and density, fire and water resistance, and other specialized characteristics.

Beta Hemihydrate

Beta hemihydrate is produced by calcining finely ground gypsum (95%–100 mesh) in vertically oriented, cylindrical steel kettles at atmospheric pressure. The calcination can be a continuous process or a batch process. Continuous calcining of land plaster is used predominantly for producing stucco for wallboard. Batch calcining is used predominantly for manufacturing construction and industrial plasters. The beta hemihydrate calcining process produces rough, fractured, fragmented particles.

In the continuous calcining process, land plaster is introduced into the top of the kettle. As the molecular water is removed during calcination, the beta hemihydrate becomes less dense and rises to the top of the kettle. The beta hemihydrate overflows the top of the kettle into a hot pit where calcination is completed and entrapped steam is released. The beta hemihydrate is discharged from the continuous kettle at 140° to 154°C .

In the batch kettle process, the calcining is done on a measured amount of land plaster, and then the entire batch is dumped into a hot pit to complete the calcination and release entrapped

steam. Batch calcining produces beta hemihydrate with high plasticity, high strength, and high density. The product from batch calcination is used for construction and some industrial plasters. Batch calcining is performed at 150° to 165°C .

Gypsum Wallboard

Several different types of wall board are manufactured, including the common variety and specialized varieties, such as fire resistant, water resistant, and plaster lath. Gypsum wall board is manufactured by mixing beta hemihydrate stucco, water, and other additives to form a slurry. Additives such as a spalt emulsion, vermiculite, chopped fiberglass, and paper fiber impart to the wallboard characteristics such as water resistance, fire resistance, and strength. The slurry is discharged onto a continuous roll of paper, the edges of the paper are folded upward, and another sheet of paper is applied to the top to form a soft gypsum "sandwich." This sandwich travels along a conveyor until the stucco slurry has recrystallized to gypsum. The continuous stream of wallboard is cut into lengths varying from 2.4 to 4.25 m. It then enters a multideck drying kiln to remove excess water. Upon exiting the kiln, the wallboard is packaged into two-sheet bundles, stacked, warehoused, and shipped to customers.

Pottery and Ceramic Plasters

Plasters used in the manufacturing of pottery and ceramic products may be alpha hemihydrate, beta hemihydrate, or a mixture of both crystal phases. White art plasters used in schools or arts and crafts classes are made from beta hemihydrate.

The process of manufacturing pottery and ceramic products involves several steps from preparation of an initial model to the final product. An original block mold is manufactured from the finished model of the product to be manufactured. Then a case mold is made from the block mold. The case mold becomes a die for fabricating multiple working or production molds. The block and case molds are typically manufactured from alpha hemihydrate. The use of alpha hemihydrate allows for the production of dense, hard, strong, and durable molds which can be intricately detailed. Working molds, which are used for mass production, are manufactured from a blend of alpha and beta hemihydrate or from alpha hemihydrate. Industrial manufacturing processes for pottery and sanitary ware involve three major types of working molds: slip-cast molds, jigger molds, and press molds.

In slip casting, a relatively fluid mixture of clay and other ceramic raw materials, called "slip," is poured into a mold, which may consist of several individual pieces. The excess water in the slip is absorbed by the plaster mold. Slip-cast molds are generally manufactured from a mixture of 15% to 20% alpha hemihydrate and 80% to 85% beta hemihydrate. Examples of slip casting include the manufacture of sinks and toilets.

In jigger casting, a relatively soft, plastic clay mixture is placed on a rotating bottom mold. As the mold rotates, an upper molding template moves downward and forces the clay to fill the bottom mold. The upper molding template also impresses or cuts the desired design elements into the clay. This method is not very labor intensive and is used to manufacture lower-priced dinnerware items. Jigger cast molds are generally manufactured from a mixture of 70% alpha hemihydrate and 30% beta hemihydrate. The alpha hemihydrate gives the mold durability and hardness for use in longer production runs.

In press casting, the clay mixture is formed into the final product by hydraulically pressing a lump of clay between the halves of a mold. This method is used to produce products such as dishes, ashtrays, some cups, and bud vases. This method of casting

is also relatively fast and low cost. The molds are manufactured entirely from alpha hemihydrate.

Alpha Hemihydrate

Alpha hemihydrate is produced by calcining sized gypsum or lump rock in an autoclave at elevated steam pressure in a batch process. This method of calcination produces dense, orderly, well-formed crystals. Alpha hemihydrate can be used alone or mixed with additives such as beta hemihydrate, portland cement, resins, and fiberglass to produce very durable products.

Industrial Prototypes and Models. Gypsum-based plaster has been used for pattern, model, and mold making for more than 1,000 years. Alpha hemihydrate cements are used to meet the specialized needs of the aircraft, automotive, foundry, plastics, and other industries. The characteristics of the alpha hemihydrate cements allow for the manufacture of molds and patterns with high accuracy, high strength, high surface hardness, and low expansion during drying and curing. Patterns and molds can be made to close tolerances such as those required by the aircraft industry.

One of the latest innovations in preparing industrial prototypes and models is the development of machineable alpha gypsum cement. USG developed this product in the 1990s to meet the needs of the rapid-prototype tooling industry; it serves as a replacement for preformed polymer-based boards. The castable alpha gypsum cement can be poured into containment vessels or molds of any size and hardens in about 1 hr. Dimensional stability is achieved after 3 hr.

This material is typically used with computer-controlled, numerical-milling (CNC) machinery to produce prototypes and models. The material can also be used to produce forms for vacuum molding of sheet plastics. Milling of cast blocks of this material produces chips rather than dust and does not require lubricating fluids.

Art and Statuary. Alpha hemihydrate gypsum cement and plaster are used to manufacture dense, durable, three-dimensional art and statuary products. Art and statuary cement and plaster can be modified by adding polymers and glass fibers to produce resilient, chip-resistant castings. These products can be used to produce solid figurines, lamp bases, and hollow statuary.

Traffic Surface Repair. Traffic surfaces such as expressways, bridges, ramps, and commercial concrete floors that carry high volumes of traffic can be repaired with a mixture of alpha hemihydrate, portland cement, and a suitable aggregate. This is a quick and effective method to repair or replace traffic surfaces that cannot be out of service for long periods.

Traffic surface repair cement expands on setting to ensure a tight contact with the surrounding pavement. This characteristic protects reinforcing steel by restricting water and salt seepage. The product sets quickly and rapidly develops relatively high compressive strength. The total process of repairing or replacing sections of pavement can be completed in less than 5 hr. The cement will develop a compressive strength of about 25 MPa within about 1 hr; the compressive strength will reach about 69 MPa after 28 days.

Architectural Applications. Fiberglass-reinforced alpha hemihydrate cement (FGR) is used to fabricate highly detailed interior architectural features. Strong, resilient, high-strength architectural details can be produced with a thickness of as little as 0.10 in. Column capitals and covers, light coves, medallions, cornices, coffers, and wall and ceiling moldings are examples of details that can be fabricated from this material. Architectural detail elements can be precast off site from original pieces to exacting detail. Historical architectural elements can be easily replicated with stronger, lightweight, FGR gypsum cement.

Medical Applications. Gypsum plasters are used in dental and orthopedic applications. Dentists use the plasters for making impressions of teeth and gums to produce bridges, crowns, and dentures.

Orthopedic plasters are used in bandages and casts to immobilize broken limbs. Newer, more innovative applications include tissue engineering where gypsum is used to promote bone and tissue regrowth. It is used as bone-void filler, in which cast pellets of high-purity gypsum provide a temporary framework for tissue regrowth (Laurencin et al. 1999). Upon setting, the gypsum has a strength of about 24 MPa. The gypsum is biocompatible, stimulates bone regrowth, and is adsorbed by the body in 4 to 8 weeks.

Deadburned Gypsum

Gypsum which has been calcined at a temperature above 400°C loses both molecules of water of crystallization, forming a deadburned calcium sulfate (CaSO_4). Although it has the same formula as anhydrite, deadburned gypsum is relatively inert and insoluble. Deadburned gypsum is almost anhydrous, with more than 99.6% of water of crystallization removed during calcination. It has a high content of elemental calcium (29% by weight).

There are several high-value-added uses for deadburned gypsum. It is used as an inert filler in plastics. It is also used in agricultural products as a binder or carrier for herbicides and pesticides. Deadburned gypsum is used in pharmaceutical products such as aspirin tablets. It is also used in pizza dough and other bakery products, acting as a desiccant and a source of calcium. The deadburned gypsum absorbs moisture in products, which then can be manufactured and stored for a period of time before use without becoming soggy.

Deadburned gypsum is used as filler in thermoplastics such as polyvinyl chloride (PVC) products: vinyl siding, window frames, moldings, conduit, and pipe. The filler imparts acid resistance and low electrical conductivity. It is also used in food packaging.

PRODUCT GRADES AND SPECIFICATIONS

There is no single statement possible on the grades and specifications of gypsum because of the diversity of products produced from the mineral. Gypsum used in construction products and food and pharmaceutical products, however, must meet stringent regulations.

Construction Products

ASTM defines the specifications for testing uncalcined gypsum and construction products manufactured from gypsum. ASTM standard C471M-01 defines the testing methods for the chemical analysis of gypsum. ASTM standard C472-99 defines the standard testing methods for the physical properties of gypsum, gypsum plasters, and gypsum-based concrete. In 1999, ASTM began to phase in a new international standard for interior and exterior gypsum wallboard products and veneer plasters that combined nine separate earlier standards. This standard titled C1396, *Specification for Gypsum Board*, eliminated inadvertent inconsistencies in the separate standards.

Food and Pharmaceutical Grade

Gypsum is an approved additive on the Food and Drug Administration (FDA) "Generally Recognized As Safe" (GRAS) listing of food additives. The use of gypsum in specific food products is described in Title 21, Part 184 of the Code of Federal Regulations (21 CFR 184.1230). The permitted amount of gypsum allowable in different types of foods is defined in the Food Chemical Codex in the United States and the National Formulary in the United Kingdom.

ECONOMIC FACTORS

Pricing

Gypsum is a low unit-value, high place-value industrial mineral, and its ultimate value is based on value-added processing. The lowest prices are for ground gypsum used for portland cement and agricultural gypsum. Calcining gypsum for use in manufacturing

wallboard or construction and industrial plasters increases the price significantly. The most valuable products include specialty dental, orthopedic, and industrial plasters; food- and pharmaceutical-grade gypsum (Terra Alba); and industrial gypsum cement. The high price per ton for gypsum used in wallboard shown in Table 6 is deceptive because the wallboard industry is primarily vertically integrated. Almost all gypsum for wallboard is produced and used internally.

Gypsum prices are regularly published in periodicals such as *Industrial Minerals* and the *Engineering News Record*. The USGS publishes average annual information for the price of crude gypsum (f.o.b. mine) and calcined gypsum (f.o.b. plant) in the United States. Groups such as Roskill Information Services and the Fredonia Group Comprehensive produce market studies of the sources, prices, consumption, and other valuable information.

Competitive Substitutes

No competitive substitutes exist for gypsum used in the manufacture of wallboard and industrial plasters. Gypsum wallboard is not a universal manufacturing material. Masonry products such as brick, concrete block, poured concrete, and cement stucco are used throughout the world.

There is no practical substitute for gypsum, anhydrite, or a blend of gypsum and anhydrite used in the manufacturing of portland cement.

Synthetic gypsum, produced primarily as a by-product of the environmental controls on coal-fired electric-power plants, is a significant substitute for natural gypsum. Most of the new wallboard plants constructed in the late 1990s and early 2000s are designed to use 100% synthetic gypsum, primarily FGD gypsum. In 2003, synthetic gypsum accounted for 26% of the total domestic gypsum supply (USGS 2004).

Packaging

Gypsum is used in more than 400 products, and therefore many different forms of packaging are used for distribution to customers. Raw ground gypsum (land plaster) for agricultural uses and portland cement rock is distributed primarily by bulk truck. Wallboard panels are loaded onto trucks or railroad cars for distribution. Construction and industrial plasters are packaged in bags.

TRANSPORTATION

Truck

Trucking is the most common method of transportation of gypsum products. It is the most flexible mode of transport, but also the most expensive. In most cases, transport is between the quarry site and the manufacturing plant, using either quarry haul trucks or over-the-road dump trucks. Truck haulage is relatively low capacity (25 t) compared to other transportation modes. The cost of truck transport is in the range of \$0.10 to \$0.25/st-mile.

Rail

Transporting gypsum by rail is relatively rare, except for the delivery of portland cement rock. The BPB North America plant in Vancouver, British Columbia, Canada, however, receives gypsum by rail from sources along the western flank of the Rocky Mountains. It is more efficient to ship the intermediate calcium sulfate hemihydrate or finished products manufactured from gypsum. Calcium sulfate hemihydrate weighs only 84.3% as much as uncalcined gypsum.

Railroad transport of gypsum is limited by factors such as the proximity of manufacturing plants to railroad lines to avoid rehandling, limited routes, and the seasonable availability of hopper rail

Table 6. Prices for gypsum by end use

End Use	Cost per Ton
Portland cement retarder	\$12.37
Agricultural gypsum	\$23.65
Wallboard	\$87.02
Plasters	\$150.98

Source: Olson 2002.

cars during grain harvest season. Capacities of railroad cars are limited to about 100 t and the transportation cost is about \$0.04/st-mile.

Barge

Most of the new wallboard plants constructed in the United States during the last decade are totally dependent on the use of FGD synthetic gypsum and were constructed adjacent to coal-fired power plants or along navigable rivers or canals to facilitate the transportation of raw materials by barge. All of these plants are located east of the Mississippi River. There is, however, relatively little natural gypsum transported by barge. Gypsum and anhydrite are supplied to portland cement plants along the Mississippi River by a single source in southeastern Iowa.

Barge transportation is relatively slow and has limited distribution capabilities. The end user must be on a waterway or within about 160 km. Transloading from barge to truck dramatically increases overall transportation costs. Climatic conditions such as drought or flooding can interrupt delivery of products by barge. Barge capacities are limited to about 1,200 t in the United States and 1,500 t in Europe. The cost of transportation by barge is in the range of \$0.0075 to \$0.01/st-mile.

Ship

Wallboard plants along the U.S. coasts receive gypsum by ship. Gypsum producers in Nova Scotia, Canada, supply wallboard plants from New Hampshire to Florida. Gypsum is also supplied to a wallboard plant and to portland cement customers on the St. Lawrence Seaway. Fundy Gypsum Company's Hantsport, Nova Scotia, ship-loading facility is at the upper reach of the Bay of Fundy and has a tidal range of 15 m. Ships with a capacity of up to 36 kt are loaded within a 3-hr period during high tide.

Mexico supplies the western U.S. coast. Large deposits midway down the Baja Peninsula on the western coast of the Sea of Cortez provide gypsum for wallboard plants from Long Beach, California, to Vancouver, British Columbia. A new gypsum quarry and shipping facility near Manzanillo in Colima on the southwestern coast of Mexico began operations in 2001.

Transportation by ship is the least expensive mode of transport for industrial minerals, about \$0.001/st-mile. Transport by ship is highly restricted, however, to coastal areas and other large bodies of water such as the Great Lakes, and requires a significant infrastructure for loading, unloading, and storage.

Import Tariffs and Custom Duties

The U.S. International Trade Commission's Harmonized Tariff Schedule of the United States contains information on import tariffs and duties for raw and processed gypsum. There are currently no general or special import duties on raw gypsum, anhydrite, or calcined plaster products.

By-Products and Coproducts

Wallboard and plaster products account for 90% of the total consumption of gypsum in the United States. Agricultural gypsum

and portland cement rock account for most of the remainder of gypsum consumption. Although some operations specifically produce agricultural or portland cement rock, in most cases these are coproducts associated with the mining and crushing of gypsum for wallboard.

Depletion Allowance

The depletion allowance is an annual, taxable-income deduction to allow mining companies to locate and develop additional ore bodies (Peters 1976). The depletion allowance on domestic gypsum production and foreign gypsum imports is 14 %. Two methods of computing the depletion allowance are allowable in the United States. In the cost or unit depletion method, the total cost of acquiring a mineral property is prorated into the total tons or units extracted from the property during mining. In the percentage depletion method, the most common method used, a specific percentage of the mine's gross income is deducted annually. The deduction, however, may not exceed 50% of the before-depletion net income.

REGULATORY AND ENVIRONMENTAL CONSIDERATIONS

Health and Safety

Gypsum mines and quarries are regulated by numerous local, state, and federal agencies regarding health and safety. In the United States, the predominant agency is the Mine Safety and Health Administration (MSHA). Calcining and manufacturing operations are regulated by the Occupational Safety and Health Administration (OSHA) and, in some cases, state agencies such as CalOSHA in California. Explosives are regulated by the federal Bureau of Alcohol, Tobacco, and Firearms (BATF).

Land Use and Zoning

Underground gypsum mining does not generally affect the concurrent use of the overlying surface. In most cases, the overlying land use is agricultural or forest. Gypsum companies that operate underground mines generally own the mineral rights for gypsum and anhydrite, but not the surface rights on a majority of the mined land and reserves.

The gypsum companies usually own the quarried land. As quarrying progresses, the depleted areas can be concurrently reclaimed and converted to pasture. USG's Alabaster, Michigan, operation has created a significant amount of wetlands in depleted quarry areas.

Mined Land Reclamation

Gypsum mines and quarries tend to be very long-term operations, and some operations in the United States have been continuous for 100 to 150 years. Gypsum quarrying in Nova Scotia began in the 1700s and continues to the present. A large area of the mined lands was disturbed before the promulgation of local, state, or federal reclamation regulations. Modern mining, however, requires a comprehensive reclamation plan and activities to minimize the impact to vegetation, hydrology, slope stability, flora, and fauna, and so forth.

Financial surety is required for the future costs of reclamation. The cost for reclamation is estimated for the fulfillment of the obligations of the approved reclamation plan by a third party. The financial surety covers the government's cost of hiring a third-party contractor if the mining company goes out of business or is otherwise unable to perform the reclamation activities in the approved plan.

Concurrent reclamation may be possible in some areas. After quarrying, the overburden stripping spoil from another area can be placed in the previous cut, covered with topsoil, regraded, and

revegetated. Reclaimed acreage can be released from financial surety upon satisfactory completion of criteria set forth by the regulatory agency.

Pollution Control

Gypsum mining and processing are less environmentally sensitive than many other types of mining industries such as coal, gold, and copper. There is no acid-mine drainage as in a coal mine; chemicals such as sodium cyanide used in heap leaching of gold ore are not used in gypsum processing.

Storm-water management plans are required for the control, storage, and treatment of surface runoff containing fuel, lubricants, antifreeze, etc. Environmental controls are necessary for storing fuel and lubricants, including aboveground storage tanks with secondary containment structures such as berms or metal pans.

Fugitive-dust suppression and control is required for drilling equipment, haulage roads, crushing and screening plants, and load-out facilities in the mining and milling phase. Dust is collected throughout many of the calcining and manufacturing phases of wallboard and plaster production.

Local and state agencies such as a county air-pollution control district or a state department of environmental protection usually enforce air and water quality regulations.

Closure and Decommissioning

Several gypsum wallboard plants and mining operations have been permanently closed and reclaimed in recent years. Dismantling calcining and manufacturing plants is similar to most industrial facilities. The total deactivation of underground mines requires removing mobile equipment (if possible), draining fluids such as fuel and lubricants from mobile and stationary equipment, and removing transformers. These activities reduce the potential contamination of groundwater as pumping ceases and the mine fills with water. All mine entrances are permanently sealed. Subsidence monitoring may be necessary if there are long-term stability issues associated with the mine structure or flooding of the mine.

Surface mining deactivation includes similar activities for removing mobile and stationary equipment, fuel and lubricant storage facilities, and explosives. Access to quarry workings is limited by berms, boulders, fences, and other measures. The angle and height of quarry highwalls are reduced by blasting to form rubble slopes and to reduce the overall final slope.

OUTLOOK AND FUTURE TRENDS

There is no foreseeable shortage of either gypsum or anhydrite resources in the United States or the world. Paradoxically, there are instances where it may be difficult to find gypsum that can be considered economic at a given time and location, a problem that has its roots in place value. The best evidence of this situation is that the United States historically has imported 33 % to 36 % of its needs from Canada, Mexico, Jamaica, the Dominican Republic, and Spain.

Almost all the imported gypsum (with the exception of a few thousand kilotons of special-grade rock) is used by wallboard plants on the Atlantic, Pacific, and Gulf coasts of the United States. The basic reasons for this situation are as follows: (1) large markets for gypsum products are concentrated in and around the coastal cities, (2) there are no developed and producing gypsum deposits along any of the three U.S. coastlines, and (3) large gypsum deposits exist on or near deep water of the exporting countries. It costs less to ship rock from the exporting countries to these major markets than to ship it from inland desposits in the United States.

It is likely that these conditions will persist into the future. The industry has been built around these facts and has made large investments in offshore deposits, shipping facilities, and domestic port locations with appropriate marine rock-handling equipment. There is no import duty on crude gypsum rock, but duties are placed on processed gypsum, although continuing free-trade agreements and laws may change the duties.

Because of its wide spread occurrence and huge potential reserves, and also because its uses are such that it is not basic to survival in a national emergency, gypsum is not considered a strategic mineral. This has permitted natural economic factors to prevail in the development of the mineral worldwide, which overall is a healthy situation that should continue to prevail.

Competition between manufacturers of gypsum building products, and from manufacturers of substitute materials, has resulted in a continuing pressure to improve the quality of gypsum products. In turn, mine operators continually strive to reduce the quantity of impurities (increase the gypsum purity) and to maintain a consistent feedstock purity. Wallboard can be manufactured from gypsum with an average purity of about 70% to 100%. Manufacturing processes, however, are designed for consistent gypsum purity, whether low or high; frequent variations in the purity are intolerable. To date, the set objectives are accomplished by (1) selective mining techniques, (2) crushing and screening to the proper size-fractions to remove impurities and maximize the average feedstock purity, (3) blending during the mining cycle on quarry benches or mine faces, and (4) blending from crusher-feed stockpiles. In some cases, heavy-media beneficiation is used to remove anhydrite or dolomite impurities.

Processing of gypsum is energy intensive; energy requirements represent the largest single cost in the production of gypsum wallboard. Conserving energy meshes well with using synthetic gypsum from power-plant desulfurization processes, because waste heat from the power plant can be used in gypsum processing.

Gypsum mining does not result in some of the environmental issues that are commonly associated with mining, such as acid-mine drainage, contamination of surface water or groundwater heavy metals, or the use of cyanide in heap leaching. Gypsum mines and quarries are regulated by numerous local, state, and federal agencies for compliance with environmental and safety regulations.

Most states require the approval of an operating plan and/or reclamation plan by local, state, and/or federal agencies for mines and quarries. The approval of the reclamation plan requires the posting of financial surety to ensure that the plan will be implemented by the applicant or by a third party if the applicant abandons the mining site. Storm-water runoff management plans are generally required to control the introduction of potential pollutants, such as oil, grease, fuel, and antifreeze, into the surface water or groundwater aquifers. The transportation, storage, and use of explosives is permitted and controlled by the federal B ATF. Undisturbed areas may require baseline studies to determine the presence of threatened or endangered species of flora and fauna, and a plan to mitigate the disturbance of their habitat, if present, during reclamation. Alternatively, acquisition of additional property with suitable habitat conditions might be required. Revegetation of reclaimed areas may be required with periodic monitoring to determine the degree of success in the reestablishment of vegetation. State or federal agencies, such as the U.S. Fish and Wildlife Service, are involved in the evaluation of the biological impacts of mining. The U.S. Army Corps of Engineers and various state departments of natural resources are involved if mining activities potentially affect stream courses or wetlands. Cultural resources are evaluated by archaeologists and reported to state agencies for historical preservation.

Synthetic Gypsum

The usage of synthetic gypsum in the United States increased by 156% between 1998 and 2002: about 3 Mt was used in 1998, and the estimated usage in 2002 was 7.7 Mt. In 2003, synthetic gypsum accounted for 26% of the total domestic supply (USGS 2004). Synthetic gypsum is derived primarily from the FGD of high-sulfur-content coal at power plants. Minor amounts are made as a by-product of chemical processes, such as the production of citric acid, sugar from sugar beets, and titanium dioxide. Phosphogypsum, derived from manufacturing fertilizer, is not used in wallboard manufacturing because radionuclides and radon are present. The majority of the new gypsum wallboard capacity constructed in the United States since the late 1990s is dependent on FGD synthetic-gypsum sources, and new plants are close to the power plants or on navigable waterways.

Recycling

Waste wallboard is generated from (1) manufacturing, (2) new construction, (3) renovation, and (4) demolition. Manufacturing waste can be recycled into the raw-material stream. The wet wallboard waste can be disaggregated into the board core and paper fiber, both of which are used in manufacturing wallboard. New construction and renovation generate 10% to 12% of wallboard scrap. The disposal costs for new construction and renovation wallboard scrap in solid-waste disposal landfills are increasing. Scrap wallboard waste generated during new construction can also be pulverized for application as a soil amendment. Demolition waste, however, is often mixed with other materials such as lumber, nails, and fiberglass insulation, and therefore cannot be recycled effectively.

New Products

The most popular size and type of wallboard will continue to be the paper-clad sheet with dimensions 1.2 m × 2.4 m × 12.7 mm. New types of gypsum wallboard are expected to grow in popularity. For example, fiber gypsum board, a nonpaper face and back board, incorporates a homogeneous blend of gypsum and paper fiber for abuse-resistant wall and floor underlayment applications. Another example is a gypsum wallboard using fiberglass scrim to replace the facing and backing paper, which is gaining acceptance in water-resistant sheathing applications.

Iodine

Stanley T. Krukowski and Kenneth S. Johnson

INTRODUCTION

Iodine is a heavy, grayish-black crystalline solid with a metallic luster. It has a density of 4.9 g/cm^3 , and is a solid at ordinary temperatures. It is a member of the halogen family, along with fluorine, chlorine, bromine, and astatine. Iodine melts at 114°C , and at 184°C it will volatilize to a blue-violet gas that has an irritating odor. It is only slightly soluble in water, and its solubility increases with temperature. At low temperatures, iodine is made up of diatomic molecules and readily dissociates, or sublimates, at moderately elevated temperatures.

Iodine is the heaviest of the halogens, and generally is less reactive than the others. Iodine, however, does not occur as an element in nature but occurs as iodates, iodides, or other combined forms. It is the 47th most abundant element in the earth's crust. It is a mild oxidizing agent in acidic solutions. Moist iodine vapor rapidly corrodes metals, with the exception of titanium and molybdenum stainless steels.

Bernard Courtois discovered iodine in 1811, after observing an unknown substance in the crude soda ash that resulted from the burning of seaweed. Samples of this unknown substance were identified to be a new element, and in 1813 Gay-Lussac named the substance *iode* in French, from the Greek word *ioeides*, meaning violet-colored.

Most people are aware of iodine as a dietary supplement in iodized table salt to prevent goiter. It is also remembered for its use as an antiseptic and disinfectant (tincture of iodine) found in first-aid kits and most medicine cabinets. The uses of iodine, however, are much more diverse. It is used, for example, in animal feed, photography, catalysts, and other applications.

GEOLOGY AND MINERALOGY

Compounds of iodine are minor constituents in seawater and brines, in certain marine organisms, and in minerals of the Chilean nitrate deposits. Sea water contains approximately 0.05 ppm iodine, and certain marine organisms, such as seaweed, sponges, fish, and some brown algae, are able to further concentrate iodine (Lyday 1999). Some seaweed can extract and accumulate iodine up to 0.45 % of their weight, on a dry basis.

The northern Chilean nitrate deposits in the Atacama Desert contain the following iodine minerals: lautarite, $\text{Ca}(\text{IO}_3)_2$ (calcium iodate); dietzeite, $\text{Ca}_2(\text{IO}_3)_2 \cdot (\text{CrO}_4)$ (calcium iodate-chromate); and bruggenite, $\text{Ca}(\text{IO}_3)_2 \cdot \text{H}_2\text{O}$ (Erickson 1981).

Various subsurface brines also contain iodine compounds. Some gas-field brines in the United States and Japan locally contain 30 to 1,300 ppm iodine. Several coals in Germany also contain iodine compounds.

Iodine has been recovered from brines mainly in Japan and the United States, but also in Java, Indonesia, Italy, England, and the former Soviet Union. Iodine has also been recovered from seaweed in China, Ireland, Scotland, France, Japan, Norway, and the former U.S.S.R. Seaweed was a major source of iodine for the world before 1959 (Lyday 1986), and it remains a large resource (Lyday 2004). For a more detailed discussion on iodine production from seaweed, see Lyday (1986). The reserves and future resources of iodine are large, even excluding the resources in seaweed and sea water (estimated by Lyday [2004] at 34 Mt), and are shown in Table 1.

Desert Evaporites

Originally, iodine was obtained mainly as a by-product during production of sodium nitrate fertilizer from caliche (*salitre*) deposits in the Atacama Desert of northern Chile. Today, however, it is produced as the primary product, or coproduct, of a process that extracts iodine from abandoned (unmined) nitrate ores and from nitrate tailings that remain from earlier nitrate mining (Velasco and

Table 1. Crude iodine: World mine production and reserves, thousand kg

Country	2002	2003*	Reserves

Gurmendi 1988). The nitrate fields are mainly in the Central Valley of Chile, called the Pampa del Tamarugal, which lies between the relatively low Coastal Range on the west and the high Andes Mountains on the east. The nitrate fields are mainly in Tarapaca and Antofagasta provinces.

The iodine-bearing nitrate ores—described by Erickson (1981, 1983), Erickson and others (1989), Garrett (1985), and Lyday (1985, 1999)—are extensive, and occur in a belt several hundred kilometers long and tens of kilometers wide. Caliche ore layers typically are 1 to 3 m thick, flat lying or gently dipping, and near the land surface. They contain evaporite minerals as cement in relatively unconsolidated surface materials, or as veins and impregnations in bedrock. The caliche is typically 5% to 30% sodium nitrate, and it contains iodine as calcium iodate (lauterite and dietzeite) in concentrations averaging 0.04% to 0.06% (Erickson 1983; Lyday 1999). Crushed caliche and tailings are leached to produce a solution containing sodium nitrate and calcium iodate (Lyday 1999). After precipitation of the sodium nitrate, the remaining liquid is then stripped of iodine.

The origin of the nitrate deposits is explained chiefly as a result of the uniquely favorable environment in which they were accumulated and preserved, rather than to any unusual source of saline materials. The essential conditions of this environment include an extremely arid climate (average annual rainfall less than 0.01 cm); slow accumulation of materials starting in late Tertiary (Miocene) through Quaternary times; and a paucity of nitrate-utilizing plants and soil microorganisms. The two chief sources of ordinary saline constituents (borate, sulfate, chloride, sodium, calcium, magnesium, and potassium) are water-soluble saline minerals in the volcanic rocks and volcanic emissions of the Andes Mountains, and particulate salts of evaporated spray from the Pacific Ocean (Erickson 1983; Harben and Kuzvart 1996). The former are leached by rainwater and carried into the desert by streams and groundwater; the latter are wind-transported into the desert.

The origin of the more exotic constituents (nitrate, iodate, perchlorate, and chromate) is less well understood. Nitrates originate from nitrogen compounds from ocean spray, and from photochemical and electrochemical reactions in the atmosphere; most, however, were probably formed by fixation of atmospheric nitrogen by microorganisms in desert playa lakes and associated moist soils (Erickson 1983). Initially, therefore, nitrates were associated with playa lakes, but subsequent to wind deposition, they were leached and redeposited by meteoric waters. The result was abundant, high-quality nitrate ore deposits that had undergone a secondary enrichment of sorts on the lower slopes of nearby hills. Perchlorate may have been formed by photochemical reactions between chlorine and ozone in the atmosphere; chromates may be the result of leaching large volumes of Tertiary and Quaternary volcanic rocks in the Andes (Erickson 1983).

The sources of iodine are most likely iodine-rich organic films on the sea surface, or gases and sublimates associated with Andean volcanism. From the former, iodine evaporates as a gas into the atmosphere or evaporates as a gas from ejected seawater spray. Iodine from the latter, in part, would be transported by surface waters and groundwater into the nitrate region. In both cases, the iodine would later be oxidized to iodate, probably by photochemical reactions in the atmosphere or at ground level on soil surfaces in the nitrate fields (Erickson 1983). Erickson (1983) also suggests the concentration of iodine by microorganisms in the playa lakes associated with the nitrate deposits.

Subsurface Brines

About 45% of the iodine currently consumed in the world comes from brines processed in Japan, the United States, the Common-

wealth of Independent States (CIS), and Indonesia (Lauterbach et al. 2001). In Japan, iodine is produced from brines associated with natural-gas wells. The iodine content of Japanese subterranean brines ranges up to 150–160 ppm. Iodine production in the United States comes from deep-well brines associated with petroleum and natural-gas fields. Iodine content in older iodine-producing rock formations in North America can range up to 1,500 ppm, but typically the iodine content of produced brines is about 300 ppm. Iodine production in the CIS is associated with oil recovery, principally in Turkmenistan, Azerbaijan, and Russia, which account for 97% of the total CIS production (Lauterbach et al. 2001; Lyday 2004). Uzbekistan also produces minor amounts of iodine.

In Indonesia, iodine is present with trace amounts of bromine in oil-field brines in Pliocene sandstones and diatomaceous marls in the Gujangan anticline (Lyday 1985); however, Indonesian iodine typically comes from brines not associated with oil and gas deposits (Lauterbach et al. 2001). The relatively small amount of iodine produced is consumed domestically.

The major iodine-producing area in Japan is the southern Kanto gas field, which extends over Chiba, Tokyo, and Kanagawa prefectures, along the east-central coast of the main Japanese island of Honshu. This area accounts for more than 80% of Japanese iodine production. Almost all the reservoirs of natural gas are found within the sedimentary basin of the marine Kazusa Group (Late Pliocene to Middle Pleistocene). The Kazusa has a maximum thickness of 2,800 m (8,535 ft) and is characterized by “remarkable changes in sedimentary facies and thickness in lateral extent” (Fukuta and Fujii 1982). It is composed of predominant siltstone and sandstone facies, with some conglomeritic and muddy facies of bathyal and/or outer-neritic environments. The major iodine reservoirs occur in the middle Kazusa in the Kiwada, Otadai, and Ume-gase formations, but some iodine brines are also produced from the lower Kazusa. Based on the geochemistry of the iodine-rich brines, Fukuta and Fujii (1982) concluded that the origin of the iodine is closely related to the depositional environments.

About 13% of Japanese iodine production comes from natural-gas fields in Niigata Prefecture, located on the shore of the Sea of Japan toward the north end of Honshu Island, 250 km north of Tokyo. This area accounts for more than 75% of Japan’s production of natural gas. Natural gas is produced from reservoirs of uncompacted sands and gravels, and semiconsolidated sandstone beds, in a sedimentary sequence of terrigenous clastics that were continually deposited from the Late Pliocene to latest Pleistocene. The Pleistocene sediments may be up to 2,000 m thick. The major stratigraphic units in this sequence include (from oldest to youngest) the Pliocene Shiiya Formation, the Pleistocene Nishiyama and Haizume Formations and the Uonuma Group. Environments of deposition range from marine to estuarine or lagoonal. These sediments form a north-plunging trough flanked by structural uplifts. Major gas-producing reservoirs vary in thickness from 10 to 35 m and are composed mostly of fine to medium sands, some containing gravel. Iodine content of the brines has a range up to a maximum of 150 ppm (Fukuta, Nagata, and Fujii 1982).

The Sadowara gas field is located along the eastern coast of southern Kyushu Island. Iodine is contained in brines associated with the production of natural gas from the Sadowara and Tonogori members (Late Pliocene) of the Miyazaki Group. These are predominantly sands, with some silty bands in the Tonogori, and represent an outer-neritic environment of deposition (Fukuta and Fujii 1982).

The Okinawa gas field in southern Okinawa-jima has potential for future production of natural gas and iodine. The lowermost Tomigusuku Formation (Late Miocene to Early Pliocene) in the Shimajiri Group (Late Miocene to Early Pleistocene) is 1,000 m

Adapted from Johnson 1989.

Figure 1. Generalized north-south structural cross-section through the Anadarko Basin of western Oklahoma. Iodine-rich brines are produced from basal Pennsylvanian sandstones on the north flank of the basin.

thick, consists mainly of sandy and silty members, represents a shallow marine bathyal environment, and is known to contain substantial natural gas and iodine (Fukuta and Fujii 1982).

Iodine also has been identified in the Ishikari gas fields on Hokkaido. Total recoverable iodine reserves in Japan were estimated at about 10 billion kg (Harben and Kuzvart 1996); however, subsequent estimates by Lyday (2004) put the Japanese reserves at 4.9 billion t (Table 1).

All iodine production in the United States now comes from iodine-rich (300 ppm iodine) natural brines in the deep subsurface of the Anadarko Basin of northwestern Oklahoma (Figure 1). Oklahoma's first iodine operation opened early in 1977. Discovery of iodine-rich brines at Woodward, Oklahoma, resulted from a 12-year program of analyzing brine samples collected by Amoco Production Company (Cotten 1978). Amoco noted unusually high concentrations of iodine in the Woodward area, with concentrations as high as 1,560 ppm in Chesterian (Mississippian) limestones and 700 ppm in Morrowan (basal Pennsylvanian) sandstones. Morrowan sandstones in the area are as much as 100 m thick and are preserved as channel sands in a south-trending paleo valley (the Woodward trench) cut into the Chesterian surface (Figure 2). Although iodine concentrations are higher in the Chesterian strata, the Chesterian limestones have low permeability and do not yield large volumes of water. On the other hand, Morrowan sandstones here have higher permeability and yield large volumes of brine, averaging about 300 ppm iodine.

The Woodward trench has an average width of 1.6 km and a known length of about 115 km (Cotten 1978). Brine-production

wells and injection wells are 2,130 to 2,290 m deep toward the northern end of the Woodward trench. Extraction of iodine-rich brines from Morrowan sandstones in a southern extension of the Woodward trench near Vici, Oklahoma, occurs at depths of 3,000 to 3,183 m. A miniplant near Dover, Oklahoma, serves as an oil-field brine-injection/disposal site, collecting waste oil-field brines from a number of producing oil and gas wells in nearby parts of northwestern Oklahoma. These oil-field brines are processed in the miniplant, where iodine is extracted before the brines are injected into wells at the site for disposal.

PRODUCTION AND TRADE

The major iodine-producing nations, in descending order, are Chile, Japan, the United States, with lesser amounts being produced in China, Azerbaijan, Russia, Turkmenistan, Indonesia, and Uzbekistan (see Figure 3 and Table 1). Annual world production in 2002 and 2003 was, respectively, 20.7 million kg and an estimated 21.4 million kg, of which about 32% is consumed in the United States. In Japan and Chile, the production of iodine depends on production of other materials, such as natural gas or nitrates, respectively, whereas in U.S. operations (in Oklahoma), iodine is the major product recovered from natural brines. Chile has established itself as the principal world producer of iodine from its nitrate-fertilizer operations with the installation of new iodine-processing plants, and Japan has maintained its level of iodine production. Reserve estimates for China have been significantly decreased based on new information from that country (Lyday 2003, 2004).

Adapted from Cotton 1978; Johnson 1989.

Figure 2. Cross-sections showing iodine-bearing Morrowan channel sandstones preserved in the Woodward trench, which has been cut into Chesterian limestones. Datum is top of Morrowan strata (length of A-A' and B-B' is about 10 km each; length of C-C' is about 15 km).

Chile

Chile is the leading producer of iodine in the world. For many years, Japan was the leading producer, but since 1997 it ranks second behind Chile (Lyday 2000). Chile produced 11.4 million kg of iodine in 2002, and in 2003 its production was estimated at about 11.6 million kg (Lyday 2004), or about 55% of the world's production. Originally, iodine was obtained mainly as a by-product during production of sodium nitrate fertilizer from caliche deposits in the Atacama Desert of northern Chile. It has since been produced as the primary product by a process that extracts iodine from abandoned nitrate tailings (Velasco and Guzmendi 1988) and crushed nitrate ore.

The Chilean Trade Commission reported nine iodine-producing companies in Chile in 2003 (ProChile 2003). The six major producers of iodine-operating installations in Chile were SQM Yoda, S.A., a subsidiary of Sociedad Química y Minera de Chile S.A. (SQM, the largest producer of crude iodine in the world); DSM Minera, a subsidiary of Dutch State Mines (DSM) of the Netherlands; Cosayach (Compania de Salitre y Yodo de Chile), a subsidiary of Inversiones Errazuriz S.A.; ACF Minera; a joint venture between DSM Minera

and the Urruticoechea family of Chile; Atacama Minerals Chile, a joint venture between Atacama Minerals Corp. of Canada and ACF Minera; and PCS Yumbes, owned by Potash Corporation of Saskatchewan, Inc. (PCS). The others include Ecolab S.A., Franmar Ltda., and Iodinex Chile Ltda. Chile exports its iodine primarily to Europe and the United States.

Japan

Iodine production in Japan, which began in 1934, comes from iodine-bearing natural brines that are recovered along with natural gas produced in three different regions of the country (Fukuta and Fujii 1982; Fukuta, Nagata, and Fujii 1982; Fukuta 1985; Wu 1985). Production of natural gas entails coproduction of associated brines, and the iodine is then removed from the brine before disposal of the brine. The three iodine-producing regions are the southern Kanto gas field (near Tokyo, in Chiba and Kanagawa prefectures), Niigata and Nakajog gas fields (about 250 km north of Tokyo, in Niigata Prefecture), and the Sadowara gas field (Miyazaki Prefecture in southern Kyushu). Chiba Prefecture accounted for about 90% of Japanese production in 2002 (Lyday 2002). In Japan, 11 plants, operated by eight companies, produced an estimated 6.5 million kg of iodine in 2002, and their combined capacity was 9.22 million kg.

Iodine production capacity in Japan, at the time this chapter was written, was about 7,000 Mtpy. This is based on 13 facilities operated by 8 companies: Ise Chemical Industries Co. Ltd.; Godo Shigen Sangyo Co. Ltd.; Kanto Natural Gas Development Co. Ltd.; Nihon Tennen Gas Co. Ltd.; Nippon Chemicals Co. Ltd.; Teikoku Sekiyu Oil Corp.; Toho Earthtech Inc.; and Japan Energy Development Co. Ltd. The largest producers are Ise, Godo, and Nihon Tennen.

The maximum iodine content of Japanese brines is about 160 ppm. In addition, iodine has been confirmed in the southern Okinawa gas field, on Okinawa, and in the Oshamanbe and Ishikari gas fields on Hokkaido (Fukuta 1985).

Iodine-rich brines in Japan are found in Miocene, Pliocene, and Pleistocene sands and silts. Most of these sediments are of marine origin, deposited in bathyal and/or outer-neritic environments, although those in the Niigata region are sands and gravels of shallow-marine to estuarine or lagoonal origin (Fukuta 1985). The iodine-rich brines of Japan are regarded as being primarily in origin, are derived from sea water, and are limited to the younger marine sediments. The iodine-rich brines are saturated or supersaturated with natural gas (mainly methane); however, some Japanese brines saturated with natural gas may not contain iodine, because methane can be derived from the remains of a variety of life forms (including land species) that contain little or no iodine (Fukuta 1985).

United States

Iodine was first produced in the United States between 1917 and 1921, from seaweed harvested in California; after distillation to produce acetic acid, the residue was processed for potash fertilizers and iodine (Lyday 1986). The first U.S. commercial production of iodine from brines was in Louisiana between 1928 and 1932; some of the Louisiana oil-field brines contained about 35 ppm iodine (Lyday 1986). Oil-field brines in parts of California contain 30 to 70 ppm iodine (Figure 4) in the Monterey Formation (Miocene) and Repetto Formation (Pliocene); these were processed at various times between 1928 and 1966. In Michigan, natural brines containing 15 to 30 ppm iodine are present in the Sylvan Formation (Devonian) at a depth of about 1,300 m. The Michigan brines were processed mainly for bromine, and by-product iodine, by Dow Chemical Company until the wells were plugged and abandoned in 1987.

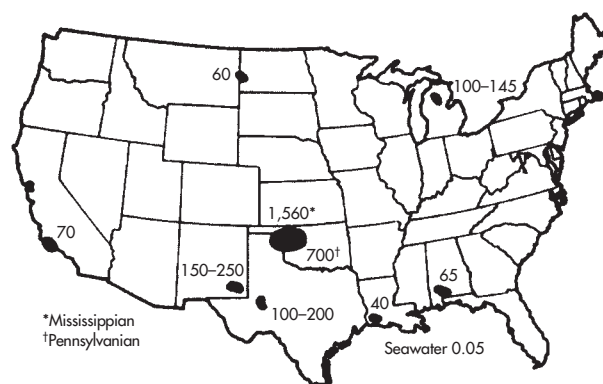

Figure 3. Countries producing iodine and estimated world production in 2003, kg

All iodine production in the United States today comes from iodine-rich (300 ppm iodine) natural brines on the north flank of the Anadarko Basin in northwestern Oklahoma (Figure 1). Oklahoma iodine production began in 1977. At present, three companies operate two major plants and one miniplant for the recovery of iodine. Total production from the three companies in 2002 was 1.42 million kg; production in 2003 was estimated to be 1.75 million kg, with an estimated value of \$19.7 million (Table 1).

Oklahoma's first iodine operation was the Woodward Iodine Corporation. It opened early in 1977 as a joint venture between Amoco Production Company and Houston Chemicals, a subsidiary of Pittsburgh Plate Glass Industries (Cotton 1978); in 1984 Asahi Glass Co. of Japan purchased the company (Lyday 1986), and then sold it to Ise in 1994 (USGS 1998; Johnson and Gerber 1999). Woodward Iodine Corporation operates 12 production wells in the Woodward trench, just north of Woodward, and injects the waste brine back into the trench through four injection wells; three additional wells are operated as disposal wells. Brine-production wells and injection wells are 2,130 to 2,290 m deep at Woodward.

Iochem Corporation of Japan started a second iodine plant near Vici in Oklahoma in late 1987. It also extracts iodine-rich brines in a southern extension of the Woodward trench, operating nine production wells and four injection wells at depths of 3,000 to 3,183 m.

North American Brine Resources (NABR) operates the remaining iodine installation in Oklahoma at a miniplant near Dover, where oil-field brines, collected from many producing oil and gas wells of northwestern Oklahoma, are processed. The company also had a major operation in the Woodward trench about 35 km north of Woodward, which included two production wells and three injection wells, at about 1,800 m deep; this facility began operations in 1989, but it is being dismantled. NABR began in 1989 as a joint venture of Beard Oil Co. (40% share) and two Japanese firms (Godoe USA, Inc., 50% share, and Inorgchem Development, Inc., 10% share) (Ohl and Arndt 1988). In 2003 NABR, as a joint venture between Mitsui & Co. of Japan and the Beard Oil Co., was

Adapted from Cotton 1978.

Figure 4. Areas of known iodine concentrations in the United States. Exceptionally high iodine concentrations, ppm, in northwest Oklahoma are in Mississippian and Pennsylvanian strata.

sold to a group of U.S. private investors and is now operated as a limited liability company (Krukowski 2004).

Other Countries

Other countries producing iodine are shown in Table 1, and they accounted for about 6%–7% of world production in 2002 and 2003 (Lyday 2004). The former U.S.S.R. had produced iodine since 1926 when borax springs at Baku (Azerbaijan) began yielding iodine as a by-product. Later, production came from oil-field brines that contained 67 ppm iodine at Lake Bejuk-Schor, near Baku. Brines in the Slavyansko-Troitsko Area of Russia are reported to contain 80 to 120 ppm iodine in the Neftechinski oil field near the Black Sea. Iodine was also produced from brines at the Nebit-Dag iodine/bromine plant in Turkmenistan (Lyday 1986), which continues to produce iodine.

Following the dissolution of the Soviet Union, the nations constituting the CIS began programs of finance reform and resource development that included privatization and private and foreign investment in their mineral industries. These programs sought investment to maintain and modernize facilities, develop new mines and processing plants, and improve worker safety and pollution controls (Levine 1995). A new iodine deposit was discovered in Astrakhan Oblast, at the Aksarai natural-gas field, and construction of a new iodine plant was planned; private and foreign investment was sought to expand and modernize the Troitsky iodine plant (Infomine Research Group Ltd. 1999). Azerbaijan proposed investment opportunities that would include construction of a plant to treat bromine-iodine waters to produce finished products (Levine 1997a). Similarly, the Ministry of Energetics and Industry in Turkmenistan sought investors for a number of new iodine and bromine production projects (Levine 1996, 1997b, 1999).

China produces iodine from seaweed resources in Shangdong, on the northern coast of Jiangsu, and in a part of Zhejiang; about 300 small companies located along the coast are dedicated to seaweed farming. Iodine is acquired as a by-product during the processing of sodium alginate from seaweed (Lauterbach et al. 2001). China has produced iodine from salt lakes at Chaerham, Yuncheng, and elsewhere, but data on this industry are not available (Lyday 1986). For a more complete discussion on iodine production from seaweed, see Lyday (1986).

The sole producer of crude iodine in Indonesia is P.T. Kimia Farma, a state-owned pharmaceutical firm with facilities near Mojokerto, East Java (Lyday 1988). In 2003, P.T. Kimia Farma added four new production wells to its iodine-production facilities, bringing the total number of iodine wells to 20. The annual production capacity thereby was raised from 150 to 200 t of crude iodine, sodium iodide, and potassium iodide (Laksamana.net 2002).

Italy produced iodine from treated mineral water at Salsomaggiore between 1925 and 1963, and during World War II iodine was extracted from coal dust in Germany and the former Czechoslovakia (Lyday 1986). Small amounts of iodine were produced from mineral waters at a depth of 1,800 m at Rabasomjen, Hungary, and as a by-product of the largest seaweed-drying plant in the world located in Iceland (Lyday 1988).

TECHNOLOGY

Exploration Techniques

Iodine production has historically been a consequence of either oil and natural-gas production or nitrate-fertilizer processing. Commercial extraction of iodine from seaweed was practiced from 1811 to 1959; however, seaweed is no longer an economical option. Cotten (1978) and Johnson and Gerber (1999) describe how Amoco Production Company approached the prospect of producing iodine from brines associated with oil and natural-gas exploration drill holes in the Woodward trench of northwest Oklahoma. Reports on the chemistry of subsurface water samples from these exploratory wells showed that a variety of potentially economic minerals were present. Feasibility studies indicated that iodine was the most favorable mineral for development, based on the fact that its concentrations were relatively high, and that the United States was almost entirely dependent on foreign imports for its supplies.

The scientists at the Amoco Research Center determined that 60,000 barrels per day of 300-ppm iodine-rich brine had to be produced over a 10-year period to be an economically viable project. Additional drill holes on 640-acre centers were drilled into the Morrow Formation (Pennsylvanian) in the trench, and their electric logs were examined to determine the thickness of water-bearing

sands with porosities greater than 10%. These criteria helped determine the concentration (grade) of iodine and the amount (reserves) of resources present. A joint venture by Pittsburgh Plate Glass Industries and Amoco Production Company brought the necessary expertise together to form the Woodward Iodine Corporation. In 1977 Woodward Iodine began producing iodine from the Morrow subterranean brines.

Harben and Kuzvart (1996) note a number of areas with similar geological characteristics to the gas fields of Japan; therefore, they are potential sources for the primary type of dissolved gas and iodine found there. Examples are in the Cagayan Valley, the southern Luzon central valley, and the Iloilo Basin in the Philippines; the Cholan Formation in the western foothills province of Taiwan; parts of East Java, Indonesia; and the southwestern part of New Zealand's North Island.

Iodine geochemical data obtained from surface soil samples are used as an exploration tool in the petroleum industry (Tedesco 1994; Tedesco and Goudge 1994; Tedesco and Andrews 1995; Leaver and Thomasson 2002). Positive anomalies of trace iodine geochemistry have been used as an indirect indicator of hydrocarbon accumulation in the subsurface. Perhaps future study of this phenomenon will lead to new exploration techniques in the search for subterranean iodine-rich brines.

Two sources of nitrate ores have been processed for their iodine in the Atacama Desert of Chile: primary nitrate ores found in caliche deposits, and *repasos*, or nitrate-mine tailings, from earlier mining operations. Exploration of these deposits consists of surface sampling of both types of ores and subsequent shallow drilling of the caliche and tailings deposits. These standard exploration practices determine the grade, the size, and the boundaries of the deposits in order to determine the mineral reserves.

Mining

Iodine produced from underground brines is pumped to the surface using electric submersible pumps and is transported to the processing facility through a system of pipelines. Natural gas is either flared off or extracted from the brines in a gas separator in which the natural gas is physically separated from the brine. The iodine-rich brine is collected in storage tanks before entering the processing plant for iodine extraction. Corrosion-resistant pipe and storage tanks are necessary to contain fluids and vapors during transport and storage; in addition, calcium-scale inhibitors are introduced to prevent calcium carbonate scale buildup from occurring on exposed metallic surfaces (W.W. Hamon, personal communication).

Mining methods in the *repasos* and nitrate ores of Chile consist of open-pit techniques. The *repasos* ore is extracted by front-end loaders or excavators and loaded into trucks for transport to heap leach piles or processing vats. Heap leaching is used where the nitrate concentration of the caliche ore is relatively low; vat leaching is used where nitrate concentrations are relatively high. Caliche-ore deposits may be ripped, or mined by conventional blasting and excavating. Heap leach piles, about 8 m high, are constructed on top of a prepared surface, which is lined with plastic to prevent contamination of the desert soils. An irrigation system pumps water onto the heap leach pads, and the resultant iodine-rich brines are pumped to a processing plant, where iodine is extracted (R.P. Clark, personal communication).

Production Process

Seaweed is no longer an economical method for the extraction of iodine. Iodine is a coproduct of sodium alginate and manitol from seaweed mainly in China. Dried seaweed is leached, obtaining an iodine solution containing concentrations of 0.5 to 0.55 g/L. This

solution is alkalinized to pH 12, then treated with sulfuric acid to produce free iodine (Lauterbach et al. 2001).

The blow-out process is the principal method for extracting iodine (I_2) from brines. Initially the brine undergoes a process consisting of skimming and settling that removes impurities such as oil, clay, and other undesirable materials. Chlorine (Cl_2) is then injected into the brine, where oxidation occurs:

The I_2 remains in solution and is extracted from the brine in a countercurrent air blow-out process in which free iodine is stripped from solution as it is exposed to large volumes of air (Johnson and Gerber 1999; Lauterbach et al. 2001).

The iodine-depleted brine is discarded or injected into wells, returning the brine to the original underground formation; this also serves to maintain fluid pressures in the reservoir and helps prevent subsidence. The iodine-rich air leaves the stripping column and enters an absorption column where the vapor is submitted to a co-current desorption process. A reducing environment is maintained by adding sulfur dioxide (SO_2) and water. The iodine is reduced to iodide:

This hydriodic- and sulfuric-acid solution is kept in an interim-storage vessel. When chlorine gas is injected into hydriodic-acid solution, it undergoes oxidation and iodine crystallization:

The oxidized crystallizer liquor is actually a mixture of water, sulfuric acid, hydrochloric acid, and iodine crystals (Johnson and Gerber 1999).

The next step separates the iodine crystals from this liquor via batch filtration, followed by vacuum drying of the filter cake. Wet iodine filter cake is transferred to a fusion kettle. Sulfuric acid, coming into contact with the melted product, helps control humidity and removes impurities. The final step converts the fused iodine into a flaked or prilled product, and then it is packed for shipping (Johnson and Gerber 1999; Lauterbach et al. 2001).

The carbon-absorption process, described in Lyday (1986) and Lauterbach et al. (2001), is used to recover iodine from brines of relatively low concentrations. Skimming and settling first separates impurities from the iodine-rich brines. This method consists of treating the clean brine with H_2SO_4 and sodium nitrite ($NaNO_2$) in large tanks:

The free iodine remains in solution and is recovered after it is adsorbed onto activated charcoal in the settling vats. The effluent acidified brine is neutralized with lime or ammonia. Hot caustic soda is used to extract the iodine from the activated charcoal, resulting in an iodate-iodide solution:

The adsorbed iodine could also be treated with potassium hydroxide (Lyday 1986):

The iodide-iodate solution is acidified with H_2SO_4 and the iodine is then separated by filtration. The resultant iodine filter cake is subsequently sublimed or directly melted and flaked.

The ion-exchange process uses anion-exchange resins packed in columns to free dissolved iodine (I_2) from their oxidized brines.

Acidified brine is treated with chlorine, liberating the iodine, which is absorbed on an ion-exchange resin. Iodine is released from the resin by elution in two steps: the first, with a caustic solution of sodium hydroxide ($NaOH$); the second, followed by a sodium chloride solution ($NaCl$) solution. The resulting elutriant solution, containing sodium iodate ($NaIO_3$) and sodium iodide (NaI), is treated with sulfuric acid in a reactor. The iodine sludge is recovered by filtration or centrifugation, then purified by sublimation or melting under sulfuric acid. The equations for the chemical reactions in the ion-exchange process are illustrated in Lyday (1986).

In Chile, iodine is recovered from brines containing iodates that are leached from nitrate ores. The iodate is reduced to iodide in a reaction tower, where SO_2 serves as the reducing agent. SO_2 is relatively inexpensive and is produced through the combustion of elemental sulfur. Lauterbach and others (2001) listed the chemical reactions involved in the process:

The iodate solution is divided into two streams—most (five sixths) passes through the SO_2 absorption tower of the iodide plant (Equation 8); the remaining one sixth is combined with the iodide solution exiting the absorption tower (Equation 9). Depending on the concentration, the result is an iodine solution or suspension, which is sent to a kerosene-extraction process where iodine is reduced to iodide with SO_2 , then recovered as concentrated iodide solution (Equation 7) (Lauterbach et al. 2001).

The iodide solutions from the iodide plant and the kerosene-extraction process are combined with iodate solution to produce iodine (Equation 9). A resulting heavy pulp contains the iodine crystals, which are introduced into a heat exchanger in which the iodine is melted under pressure. The melt flows into a reactor for settling, and then enters a second reactor for sulfuric-acid drying and refining (Lauterbach et al. 2001).

MARKETING

Uses

Iodine products were first used commercially in the early part of the twentieth century as a remedy for goiter, as a disinfectant for cuts and abrasions, and for sanitation (Lyday 1999). Since then, iodine has been used in a variety of specialty chemicals for many commercial applications. Major uses include x-ray contrast media, iodophors and biocides, catalysts, stabilizers, animal feeds, disinfectants, pharmaceuticals, photography, and colorants. It is difficult to report the end use of iodine accurately since iodine-containing intermediates are marketed before being used in their ultimate form. Table 2 gives U.S. consumption by principal end-use during 2002. The following description of uses is summarized from Lyday (1999, 2002), Lauterbach and others (2001), and Harben (2002).

X-ray Contrast Media

Because iodine absorbs x-rays, it is included in the class of drugs known as radiopaques, which are drugs used to diagnose medical problems by media contrast. Radiopaques containing iodine are introduced into the body in anatomical areas that have insufficient natural contrast. The iodine absorbs the x-rays to a greater extent than do natural soft tissues or blood, thereby casting a light shadow on x-ray film and thus enhancing the contrast. The main x-ray procedures using iodine-contrast media diagnostically are angiography, CT scans, gastrointestinal series, and colicography.

Table 2. U.S. consumption (apparent*) of iodine in 2002

Use	Thousand kg	% of Total
Sanitation	2,934	45
Animal feeds	1,760	27
Pharmaceuticals	652	10
Catalysts	522	8
Stabilizers	326	5
Other†	326	5
Total	6,520	100

Source: Lyday 2002.

* Domestic production plus imports minus exports plus adjustments for government and domestic industry stock changes.

† Includes inks and colorants, photographic chemicals, laboratory reagents, production of batteries, high-purity metals, motor fuels, and lubricants.

As populations of the industrialized nations grow older—particularly in Japan, the United States, and Western Europe—there is a greater need for diagnostic testing to keep patients healthier longer and to reduce hospitalization costs (Lyday 2002). The increase in medical testing of older populations with x-ray contrast media will result in increased consumption of iodine in radiopaque drugs.

Iodophors and Biocides

An iodophor is an iodine complex weakly bound to a carrier molecule, or surfactant, which increases iodine solubility in water, permitting its gradual release and giving a residual effect to the compound (Lauterbach et al. 2001). The germicidal action of iodine results from its capacity to quickly penetrate the cell walls of microorganisms, rupturing their proteins and nucleic acid. For these reasons, iodophors and iodine-based biocides are used for their disinfectant and antiseptic properties in a variety of sanitation and cleansing applications in hospitals, dairies, laboratories, food-processing plants, and restaurants, and in dishwashing detergents, herbicides, swimming pools, and water supplies. In some instances, toxic biocides (for example, pentachlorophenol and tributyltin oxide) have been replaced with iodine-based alternatives in certain preservative applications, including cosmetics, paints, wood preservation, metalworking fluids, leather processing, inks, and starches (Lauterbach et al. 2001).

Catalysts

A major use of iodine is in catalysts. With development of the Monsanto process for producing acetic acid (using an iodide-promoted rhodium complex as catalyst) in the 1960s, about 90% of new acetic-acid capacities use this process. Acetic acid is used as a solvent in the production of terephthalic acid, a major component of polyethylene terephthalate, a plastic used for carbonated and other soft-drink containers. Iodide catalysts also are used in the dehydrogenation of butane and butene to butadiene, and in the preparation of stereoregular polymers.

Stabilizers

Iodine is used as a stabilizer in the manufacture of nylon for tire cord and carpets, and for converting rosins, tall oil, and other wood products to more stable forms.

Animal Feeds

Another major use of iodine is in the form of additives for animal feeds; about 27% of U.S. domestic consumption goes to that end use (Lyday 2002). Cattle and sheep are fed iodized salt and other

iodine compounds to regulate metabolism and to reduce certain livestock ailments such as soft-tissue lumpy jaw and goiter. Iodine supplements are especially important for breeding cows and calves. A deficiency in iodine during pregnancy and lactation increases the risk of weak births or stillbirths in cattle, pigs, and horses.

Photography

Photography is one of the oldest industrial uses of iodine. Almost all photography is based on the light-sensitive character of silver halides, particularly silver iodide and silver bromide. As much as 7% of the silver salt in the emulsions of negatives is iodide, and ammonium iodide is used as a photographic developer. The product supplied to the photographic industry is potassium iodide, which is then converted to silver iodide under proprietary processes. See Harben (2002) for more details on photographic emulsions.

Pharmaceuticals and Human Health

Pharmaceuticals are another major use of iodine (including radiopaque media, discussed previously). Potassium iodide is widely used in cough medicines as an expectorant, and iodine compounds are used in the synthesis of amphetamine, methamphetamine, ethyl amphetamine, antibiotics, corticosteroids, and other drugs.

Potassium iodide is used as a preventive of thyroid cancer. The U.S. Food and Drug Administration recommends it as a safe and effective means of blocking radioiodines from the thyroid in a radiation emergency, such as a nuclear accident. During nuclear accidents, a portion of the radioactivity is released as ¹³¹I, a major radioisotope of nuclear power plants. The Chernobyl nuclear accident released massive amounts of ¹³¹I, and several years later there was a sharp peak in thyroid cancer among children and adolescents in Belarus and Ukraine (Harben 2002).

Iodine is necessary for healthy human life. The thyroid gland requires iodine to produce the hormone thyroxine. Iodine deficiency disorder, or IDD, occurs when people lack iodine in their diets. It is especially serious for pregnant women and young children, where deficiencies may result in retarded fetal development and physical and mental retardation (cretinism being an extreme condition), respectively. The World Health Organization (WHO), United Nations Children's Fund (UNICEF), and the International Council for the Control of Iodine Deficiency Disorder (ICCIDD) have taken great strides in eliminating IDD. The major effort to ensure iodine intake is to add potassium iodide or potassium iodate to table salt and vitamin supplements. IDD may also lead to conditions such as goiter (enlargement of the thyroid gland, manifested in a swelling of the neck), abnormal physical development, and reproductive loss (Lauterbach et al. 2001).

Colorants

Iodine is a coloring agent in some dyes used in foods and materials. Red food coloring has been used in cherries, candies, carbonated soft drinks, powdered drinks, gelatin desserts, icings, and pet foods, whereas red dyes are used in dyeing or printing of cotton, half-silk, jute, and straw products. Other colorant applications include drugs, cosmetics, printer inks, and photographic sensitizers.

Other Uses

Iodine is used as an intermediate in the synthesis of fluorochemicals used in water- and oil-repellent emulsions in textiles and leather, and in fire-extinguishing foams. Iodine is also used in the modification of selenium to make semiconductors; in the manufacture of high-purity metals such as titanium, zirconium, boron, and hafnium; in the production of motor fuels; in additives in rechargeable dry cell batteries; as smog inhibitors; and as cloud seeders to induce rainfall.

Product Grades and Specifications

Iodine and its compounds are generally marketed in the form of crude iodine, resublimed iodine, calcium iodates, calcium iodide, potassium iodide, sodium iodide, and numerous organic compounds.

Commercial-grade crude iodine normally has a minimum purity of 99.5% I_2 ; the main impurities are water, sulfuric acid, iron, and insoluble materials (Lyday 1999). Specifications of the U.S. Pharmacopoeia XVII call for crude iodine to be not less than 99.8% I_2 .

Resublimed iodine is usually 99.9% pure, and American Chemical Society (ACS) specifications call for not more than 0.005% total bromine and 0.020% nonvolatile materials (Anon. 1971).

Prices

Actual prices for iodine are negotiated on long- and short-term contracts between buyers and sellers (Lyday 2002). U.S. prices for iodine (including cost, insurance, and freight charges for imported iodine) have fluctuated since peaking at \$17.46/kg in 1988 (Johnson 1994). Prices decreased because of factors such as economic recession (1989–1992; 2002–2004) and oversupply (for example, when Chile began increasing production in the early 1990s and at the turn of the century). Trends that caused prices to increase were additional demand for x-ray contrast media, potassium-iodide production for U.S. government contracts, and efforts to eliminate the effects of IDD. U.S. producers believed that large inventories of iodine, sold by the National Defense Stockpile since 1989, depress the price of iodine produced domestically; domestic production is competing with about 1 million lb of excess stockpile (Lyday 2002). Figure 5 shows the price trends for 1977 to 2001 (Lyday 2002).

Substitutes

Chlorine and bromine can be substituted for iodine in some chemical applications, but they are less desirable. Antibiotics, boron, chlorine, bromine, and mercurochrome can be used instead of iodine in sanitation and biocide uses. Salt crystals and finely divided carbon can be used for cloud seeding (Harben 2002; Lyday 2004). There are no substitutes for iodine, however, in some cattle feed, catalytic, nutritional, pharmaceutical, and photographic uses (Lyday 2004).

Recycling

Harben (2002) reported that there is virtually no recycling of iodine; however, Lauterbach and others (2001) reported that several iodine-consuming companies recover iodine from side streams generated in their production processes. Iodine is recovered as a derivative from the incineration of process impurities that have been captured before being discharged into the environment.

U.S. Consumption, Imports, and Exports

Reported U.S. apparent consumption of iodine increased from 6,140,000 kg in 1999 to 6,650,000 kg (estimated) in 2003 (Lyday 2004); however, consumption was down in 2001 (3,650,000 kg) and 2002 (4,780,000 kg). A breakdown of consumption and uses during 2002 is presented in Table 2. In 2003, about 5,800,000 kg (estimated) was imported to the United States and about 1,150,000 kg (estimated) was exported. U.S. imports from 1999 to 2002 were from Chile (66%), Japan (30%), Russia (2%), and other countries (2%).

Packaging and Transportation

Crude iodine is shipped in double polyethylene plastic-lined fiber drums holding 45 to 90 kg each. Resublimed iodine is also shipped

Figure 5. Iodine price trends from 1977 to 2001

Table 3. Tariffs on iodine (2004)

Item	Number	Normal Trade Relations 12/31/03
Iodine, crude	2801.20.00	Free
Iodide, calcium and cuprous	2827.60.10	Free
Iodide, potassium	2827.60.20	2.8% ad valorem
Iodides and iodide oxides, others	2827.60.5000	4.2% ad valorem

Source: Lyday 2004.

in the same type of container, and in 11.3-kg glass jars and smaller bottles. Iodine is also shipped in 350-kg bulk bags and 1,800 -kg tote bags, depending on the mode of transportation.

The mode of transportation depends on the plant location, the infrastructure of the region, and the destination of the product. In Oklahoma, for example, iodine is shipped by rail and truck and can accommodate bulk shipments of fiber drums, bulk bags, and tote bags. For destinations along major waterways and overseas, barges and cargo ships, respectively, are the norms. Freight classification is "chemicals, not otherwise indexed by name" (NOIBN) and requires no special label.

ECONOMIC FACTORS

Depletion Allowances, Tariffs, and Stockpiles

The depletion allowance for iodine from both domestic and foreign production is 14%. Tariffs on iodine are reported in Table 3. Since 1989, the U.S. government Defense National Stockpile Center (DNSC) has sold surplus iodine stocks at about 454 tpy (1 million lb/year). These are released quarterly and sold at the prevailing market price.

REGULATORY AND ENVIRONMENTAL CONSIDERATIONS

Health and Safety

Unlike other halogens, iodine is relatively safe to handle because it is a crystalline solid at normal room temperature and pressure; it has a relatively low vapor pressure (1 kPa at 25°C) compared to other halogens (for example, 700 kPa for chlorine). Personal protective equipment (PPE) is not necessary when handling properly packaged containers; however, chemically approved gloves, clothing, eyewear, and masks or respirators should be worn when solid iodine is not packaged properly (Lauterbach et al. 2001).

An upper limit of 0.1 ppm iodine in air was set by the Occupational Safety and Health Administration because unprotected short-term exposure (up to 1 hr) can be hazardous to lungs and eyes. Severe irritation to the eyes and respiratory tract, which may lead to pulmonary edema, can occur from exposure to concentrations above 0.1 ppm over extended periods of time. Burns may also result if there is prolonged contact with the skin. Chronic absorption of iodine results in iodism, a condition whose symptoms include insomnia, inflammation of the eyes and nasal passages, bronchitis, tremors, diarrhea, and weight loss (Lauterbach et al. 2001).

Land Use and Zoning

Permits for brine wells are similar for oil and natural-gas wells, particularly if there is coproduction of these resources or if injection wells are part of the iodine-extraction operation. Most iodine operations are located in remote areas, so industrial zoning is not a major concern. When iodine-producing brine wells must be abandoned, the boreholes are plugged with concrete to seal producing formations to prevent contamination of water aquifers, other rock units, and the soils where the drill pad was located.

Pollution Control and Other Environmental Considerations

In the production of iodine, special considerations for chemical reagents such as chlorine, sulfur dioxide, ammonia, and sulfuric acid must be taken into account and documented in risk-management plans. This includes emissions from nonpoint sources (fugitive emissions) and single-point-source emissions. Fugitive emissions are those from leaking valves, corroded pipe, and others. Point-source emissions would be equipment (such as natural-gas compressors, boilers, and scrubbers) discharging noxious substances (usually as gases) into the environment.

In the United States, the Environmental Protection Agency requires that risk communication be filed with appropriate governmental entities. The Superfund Amendments and Reauthorization Act of 1986 (SARA Title 3; also known as the Right-to-Know Act of 1986) sets forth guidelines for essential emergency planning for local communities. Potential chemical hazards are identified by the producer, who files various risk communications annually with the local emergency committee, fire departments, departments of environmental quality (in Oklahoma, for example), and others. This notifies the respective agencies of potential problems associated with hazardous materials used at the site or plant.

In the United States, iodine is a federally regulated List II chemical under the Comprehensive Methamphetamine Control Act of 1996, so iodine producers are required to report to the Drug Enforcement Agency and other enforcement authorities all iodine buyers and customers. Iodine is an essential ingredient in the manufacture of methamphetamines, which are commonly produced illegally (sold as "meth" or "speed"). These customs requirements, therefore, call for iodine sellers to record all sales and to report detailed information about their customers. As a result, producers maintain tight control over their inventories and have increased security at warehouses and other storage facilities.

OUTLOOK AND FUTURE TRENDS

The 2000 Nobel Prize in chemistry was awarded for research that showed that oxidizing thin films of polyacetylene with iodine vapors increased their conductivity a billion times. This converted the polyacetylene from insulator to semiconductor. Applications related to electroluminescence will allow developments in ultrathin color screens for video and television. Other developments include advantages where the avoidance of static electricity is important (e.g., synthetic carpets and computer screens, corrosion inhibitors,

lightweight automobile batteries, electromagnetic shielding, and artificial nerves and sensors) (Lauterbach et al. 2001).

The popularity of digital imaging would seem to decrease the use of wet-processing film imagery; however, although digital video of live events, game shows, and other television broadcasts is recorded digitally, 75% to 85% of all televised programs in prime time are recorded on 35-mm motion-picture film. Most feature films also are photographed using 35-mm film. The use of iodine in films and processing may be limited to specialty imaging in the future as the cost of digital-imaging equipment decreases and recording, storing, and imagery reproduction increases in quality (Lyday 2002).

The use of fluoroiodocarbons has been identified as a replacement for halogen-based fire-suppression systems. The Montreal Protocol banned the production of some environmentally unfriendly chlorofluorocarbons, halons, and other ozone-depleting chemicals. This has opened a new area of research for the use of iodine compounds (Lauterbach et al. 2001; Lyday 2002).

The use of potassium iodate and potassium iodide in table salt has increased the use of iodine to alleviate the effects of IDD, especially in India and China. The largest inorganic-chemical complex in Asia is located at Mithapur, Gujarat, India. It produces iodized vacuum salt and is India's largest producer of iodized salt (Hamel 2003).

The use of iodine in individual water-purification systems in developing countries (Chile and Mexico, for example) represents a new application of a historical purification process. This should also consume large amounts of iodine in the future (Harben 2002; Lyday 2002).

Finally, the demand for diagnostic testing of an aging population in the industrial nations (Japan, North America, and Western Europe) is responsible for the increased use of iodine-based x-ray contrast media (Lyday 2002). Also, an additional market is developing in China for diagnostic equipment as the Chinese economy continues to grow. The giant market potential in China for all sorts of materials and goods, including industrial minerals, will have a noticeable effect on the demand for iodine in the future.

Kyanite, Andalusite, Sillimanite, and Mullite

Palmer C. Sweet, Guy B. Dixon, and John R. Snoddy

Kyanite, andalusite, and sillimanite are naturally occurring anhydrous aluminum silicate minerals. Each has the same chemical formula, Al_2SiO_5 , but differing crystal structures. These variances in crystal structure give somewhat unique physical properties to each of the three minerals, and each is used in slightly different ways by modern industry. Mullite is a very rare mineral named for its discovery site on the Scottish Isle of Mull. Mullite, although seldom found in nature, can be artificially produced by heating any number of aluminum silicate minerals in certain proportions to the correct temperature. Synthetic mullite is classified as an aluminum silicate, and is addressed as such in this chapter.

The world's largest producer of kyanite is Kyanite Mining Corporation (Dillwyn, Virginia) in the United States. This company mines two massive deposits of kyanite quartzite in central Virginia. Internationally, small amounts of kyanite are produced in Australia, Brazil, China, Ukraine, and India—but mainly by divisions of refractory companies that produce only for their own parent corporations, or by small mining companies that sell low-grade material into their own domestic market (Figure 1).

The South African Mineral Resource Committee (SAMREC) and Denain-Anzin Minerais Refractaires Ceramiques (DAMREC), the South African and French divisions of the industrial minerals conglomerate, IMERYS, dominate worldwide andalusite production. Recently, however, a new South African company, Andalusite Resources, has begun major mining and beneficiation operations in the Northern Transvaal. Andalusite (mixed with prophyllite) is also produced by Piedmont Minerals Company, an American company based in Hillsborough, North Carolina, and in small amounts by various producers in India and China (Figure 1).

Sillimanite, which is much less widely used than either andalusite or kyanite, is produced in small amounts in Australia, Brazil, India, Spain, the Republic of South Africa, and the former U.S.S.R. (Figure 1).

Synthetic mullite production is dominated by C-E Minerals (also a division of IMERYS). C-E produces its famous “Mulcoa” products by mixing and calcining the various grades of bauxitic clays that it mines at its site in Andersonville, Georgia. A fused synthetic mullite is also produced by Washington Mills Electro Minerals Corporation in Niagara Falls, New York, and by a host of smaller—mostly Asian—suppliers throughout the world. Kyanite Mining Corporation also produces a synthetic mullite product by simply calcining the kyanite that it mines and beneficiates at its operations in central Virginia.

As of early 2004, annual world production of kyanite, andalusite, sillimanite, and synthetic mullite was approximately 690,000 t (115,000 t of kyanite; 315,000 t of andalusite; 25,000 t of sillimanite; and 235,000 t of synthetic mullite in its various forms). Almost all of this production is consumed by refractory/ceramic companies that use these minerals as raw materials in their heat-resistant products.

GEOLOGY

Mineralogy

Kyanite is a blue to light-green, triclinic mineral that occurs in long, thin-bladed crystals and crystalline aggregates in gneiss, schist, and pegmatites.

Andalusite is a yellow, brown, green, or red orthorhombic mineral that occurs in thick, almost green prisms in schist, gneiss, and hornfels. Gem-quality andalusite exhibits a strong pleochroism—brownish-green in one direction and brownish-red perpendicular to it. Andalusite also occurs in placer concentrations where it has weathered out of rock.

Sillimanite is a brown, pale-green, gray, or white orthorhombic mineral that occurs in long, slender, needlelike crystals in schist and gneiss.

Chemical and Physical Properties

Table 1 presents the chemical and physical properties of kyanite, andalusite, and sillimanite. Both andalusite and sillimanite are orthorhombic, whereas kyanite is triclinic. Andalusite has a hardness of 7.5, sillimanite 6.5, and kyanite between 5 and 7, depending on the direction from which the crystal is compressed. Andalusite has the lowest specific gravity of the three at approximately 3.18; sillimanite has a slightly higher specific gravity of about 3.23, and that of kyanite is significantly higher with an average of 3.6. Kyanite is the only one of the three minerals that irreversibly expands when heated (calcined to produce mullite).

Distribution of Major Deposits

Kyanite

Kyanite Quartzite. Kyanite quartzite occurs in the Piedmont region of the Appalachians and trends from Georgia through South and North Carolina into central Virginia. The kyanite quartzite, which is in the Ordovician Arvonian Formation in Virginia, is enclosed in a sequence of metamorphosed felsic and mafic flows

Figure 1. Kyanite, andalusite, sillimanite, and synthetic mullite production

Table 1. Chemical and physical properties of kyanite, andalusite, and sillimanite

	Kyanite	Andalusite	Sillimanite
Chemical formula	Al_2SiO_5	Al_2SiO_5	Al_2SiO_5
Composition	Al_2O_3 63.2% SiO_2 36.8%	Al_2O_3 63.2% SiO_2 36.8%	Al_2O_3 63.2% SiO_2 36.8%
Type	Aluminum silicate	Aluminum silicate	Aluminum silicate
Crystal system	Triclinic	Orthorhombic	Orthorhombic
Cleavage	(100) perfect (010) good	(110) good (100) poor	(010) good
Specific gravity	3.56–3.66	3.16–3.20	3.23
Hardness	5–7	7.5	6–7
Temperature at which mullite is formed	1,100°C–1,480°C	1,450°C–1,500°C	1,550°C–1,650°C
Volume change during calcination	Sizeable increase	Very slight increase	Slight increase
Density after calcining at 1,445°C	3.05	3.04	3.10

and volcanoclastic rocks on the southeast limb of the Blue Ridge Anticlinorium. The kyanite deposits, currently being mined at Wilis Mountain and East Ridge in Virginia, were originally deposited as basal quartz gravel or coarse sand overlain by silt and clay that was later metamorphosed to form kyanite. Hydrothermal fluids were later introduced (Marr 1992). Kyanite quartzites are rocks containing 15% to 40% kyanite and usually about 5% of other minerals such as pyrite, rutile, and mica. The remainder is quartz.

The kyanite-quartzite deposits in the Georgia–South Carolina–McCormick districts seem to be similarly formed because the mineralogy, and other factors, are virtually the same as in Virginia. The metavolcanics and sediments are known as the Little River Series in Georgia, but they are considered to be in rocks of the Slate Belt in Virginia.

There are at least 13 distinct deposits of kyanite quartzite within the Appalachians. Because of their resistance to weathering, which

results in their prominence above the surrounding countryside, all of them are known as mountains. The operation at Baker Mountain, Virginia, was closed in 1979 and the one at Graves Mountain, Georgia, was closed in 1986. From 1948 through 1969, Commercialores, a subsidiary of Combustion Engineering, worked the Henry Knob deposit in York County, South Carolina.

There is a zone of metavolcanics in southeastern California and extending into southwestern Arizona whose composition and lithology resembles that of the deposits in the Appalachians. This zone contains some deposits of kyanite quartzite. The kyanite in these deposits, however, although averaging 25% to 35% of the rock, has proven to be contaminated with extremely fine inclusions of quartz. As of 2005, it was not economically feasible to produce a competitive kyanite product from these western U. S. kyanite-quartzite deposits.

Kyanite quartzite has been described in several other places in the world, and usually occurs within a geologic framework similar to that of the deposits of the southeastern United States. Such deposits have been described and explored in Surinam, Norway, Kenya, and Austria. A kyanite deposit (Lac Croche property), located 35.4 km south-southeast of Fermont in Quebec, Canada, was reportedly being evaluated. Exploration indicated a zone with 20% to 40% kyanite in large bluish crystals, 1 to 2 cm in size, and gave an early estimate of 3,711,210 t to a depth of 32.8 m (Potter 1988). Other promising Canadian deposits include one located north of North Bay in Ontario, of which Kyanite Mining Corporation owns the mineral rights.

Kyanite Schists and Gneisses. Kyanite is very common in the highly metamorphosed schists and gneisses of the metamorphic regions of the world. Typically, the kyanite occurs in quantities ranging from a percent or two to as much as 25% in a gangue of biotite, feldspar, muscovite, garnet, and occasionally hornblende and other common rock-forming minerals. Rocks containing a few percent of kyanite are extremely abundant and widespread. They are exposed over hundreds of square kilometers in the eastern and western metamorphic areas of North America and in the metamorphic rocks of other continents. Repeated attempts to recover the kyanite from such rocks have been made and were described in earlier editions of *Industrial Minerals and Rocks*. The most recent attempt was in the Timiskaming District in western Quebec by North American Refractories of Cleveland, Ohio. An earlier effort was made in the late 1950s near Burnsville, North Carolina. As of 2005, no schists were being mined for kyanite.

If such kyanite is to be economically viable, it is necessary that the region be deeply weathered and of gentle relief so that a mantle or segregation of resistant kyanite nodules, cobbles, and boulders have accumulated at the surface. It is also necessary for labor to be abundant and inexpensive.

A great deal of literature has been published by the U.S. Bureau of Mines (USBM), the U.S. Geological Survey (USGS), and agencies of other governments describing investigations of kyanite-bearing schists. The USBM conducted an exhaustive study in Idaho on the huge deposits of kyanite, andalusite, and sillimanite at Goat Mountain and the kyanite deposit on Woodrat Mountain near Kamiah, Idaho (Van Noy 1970).

Massive Kyanite. Kyanite is found locally as nodules, knots, and huge boulder-sized segregations in very highly metamorphosed areas of aluminous sediments. This has been the principal source of kyanite from India for the past 40 years. Production was estimated to be 31,339 t in 1988 (Potter 1988), but the deposit has been exhausted over the years, and as of early 2005, the deposit was no longer producing. Similar segregations were the basis for the kyanite production in Kenya.

In several counties in Georgia, similar lumps of massive kyanite are found (Furcron and Teague 1945). Although the abundance and purity of the Georgia massive kyanite lumps meet the requirements for commercial exploitation, high labor costs make economic production by hand sorting and gathering unfeasible. Production was limited to a few carloads during World War II.

Kyanite mineral segregations are probably the result of local pneumatolytic migration of silica and alumina during the late stages of regional metamorphism. Introduction of alumina does not seem to have been a factor, because the overall composition of the segregations is similar to that of the country rock if the sample area considered is large enough to include the barren quartz segregations that in variably accompany the kyanite-corundum segregations. Aside from the size and abundance of the segregations in the Lapsa Bura deposits of India, they do not seem mineralogically dissimilar from kyanite segregations found occasionally in all kyanite schists.

Massive kyanite typically contains corundum and minor amounts of rutile. The kyanite is often felty and acicular and occurs in tightly interlocking aggregates. Kyanite from India is usually produced in lumps large enough to be hand sorted according to kyanite and corundum content, and three grades are offered. Massive Indian kyanite has properties quite unlike those of coarse kyanite crystals; it is essentially volume stable and calcines to a dense white aggregate that is much prized by European refractory manufacturers. On the other hand, the coarse kyanite produced from Georgia placer deposits in the 1940s, and more recently in Kenya, crumbles and loses much of its density and physical strength upon calcining. Apparently the interlocking acicular crystal mode of Indian kyanite prevents such expansion and consequent breakdown. Between 1968 and 1973, a kyanite-sillimanite concentrate was recovered as a by-product from the processing of Pleistocene beach sands in Florida.

Andalusite

Constituent of Metamorphic Rocks. Andalusite is a frequent constituent of metamorphic rocks, although it is not as abundant or common as kyanite or sillimanite. It is found in argillaceous and micaceous slates, in schists and gneisses, and as crystals resulting from the contact metamorphism of intrusive rocks. Andalusite will readily incorporate foreign matter in its crystals, and it frequently grows around preexisting materials, including carbon. One variety, chialolite, is so named for the crosslike inclusions of carbon oriented normal to the axis of the crystal.

In France, near Glomel in Brittany, an extensive, deeply weathered body of andalusite schist is currently being mined by D'AMREC. This company has been active at the site since 1969. The quarry is approximately 966 m² long by 40 m deep. About 618,535 t of material is moved annually, and of that amount, 53,606 t is commercial kerphalite (two grades of andalusite concentrates). Of the two grades of kerphalite, grade KA contains a minimum of 59% alumina, and grade KB contains a minimum of 52% alumina (Anon. 1989). Near Glomel, the andalusite occurs as matchstick-sized crystals embedded in a fine-grained black groundmass composed of biotite, hornblende, muscovite, and feldspar. The andalusite is evenly disseminated and constitutes about 20% of the rock. The rocks in the area are poorly exposed, and the geology of this occurrence is not well understood.

An extensive deposit of andalusite schist is near Canso, Nova Scotia. The andalusite makes up about 15% of the rock and is evenly disseminated as large porphyroblasts averaging about 1.3 to 2.5 cm in cross section. The groundmass is principally muscovite, garnet, and feldspar. The crystals of black andalusite incorporate about 10% finely disseminated magnetite and muscovite, however, and beneficiation is not practical.

Near Hillsborough, North Carolina, a monadnock of andalusite-pyrophyllite-sericite is being mined by the Piedmont Minerals Company, which is now a division of Resco Products. The ore consists principally of pyrophyllite and quartz and contains 15% to 20% of disseminated pink andalusite. The andalusite is mined along with the pyrophyllite, and, being calcined in part by nature, exhibits refractory characteristics usually found only with prepared calcined materials. The product is consumed by Resco Products in the manufacture of kiln car refractories, plastic and castable refractories, firebrick, and ramming and gunning mixes.

In the Goat Mountain deposit in Idaho, andalusite coexists with kyanite and sillimanite. No attempt has been made to separate it from the aluminum silicate minerals in the tests made so far. The andalusite in this deposit typically incorporates a great many deleterious impurities. The Goat Mountain deposit is extremely large, but to date, no commercial exploitation of the deposit seems feasible because of beneficiation difficulties (Abbott and Prater 1954).

In early 1991, exploration work by Ramsgate Resources Ltd. at Spargoville, in Western Australia's Eastern Goldfield, uncovered several occurrences of andalusite-bearing chorite-biotite schist. The andalusite occurs as discrete crystals, from 0.5 to 20 cm in length, in metamorphosed aluminous meta sedimentary rocks. Reportedly the andalusite is of very high quality, equal to if not better than South African material (Anon. 1991).

In the Vihorlat Mountains of East Slovakia, Slovak Republic, secondary quartz with corundum, mullite, and andalusite is found (Hruska 1991).

Residual Andalusite. Alluvial deposits of andalusite sand occur in the Republic of South Africa. The andalusite has been weathered from the parent rock and subsequently concentrated by the action of wind and water; apparently, concentration is still going on. Preliminary figures indicate that at production was 176,901 t in 2004. Concentrate grades averaging almost 60% alumina have been obtained. Total reserves are reported to be 41.65 Mt where the andalusite is found in metamorphosed shales of the Strubenskop Formation near Zeerust, in the weathered shales of the Timeball Hill Formation at Thabazimbi, and in the hornfels and schists of the Eastern Transvaal near Penge; all these units are of the Pretoria Group and have been intruded and metamorphosed by the Bushveld Complex. Until 2003, SAMREC controlled all operational mines, including the region's largest, the Rhino mine in Thabazimbi. Combined with their operations in France, this gave IMERYS a virtual monopoly on the supply of andalusite in the world. In 2003, however, a new competitor entered the market in South Africa. Andalusite Resources, as the new supplier is known, purchased the assets of an existing mine in the Thabazimbi area and restarted production in that region. Initial capacity figures place the Andalusite Resources mine at 27,216 tpy.

Crystals. In 1986, exceptionally large reddish to flesh-colored andalusite crystals were discovered in Campbell County, Virginia. Some of the single crystals measured 25.4 cm long and up to 11.7 cm wide. They were formed through contact metamorphism along both sides of a quartz vein that has intruded a staurolite-rich muscovite schist (Giannini and Penick 1986).

Sillimanite

Sillimanite Schist. Sillimanite is a very common rock-forming mineral in metamorphic rocks of relatively high rank. It is common in a series of metamorphosed rocks to find sillimanite, kyanite, and andalusite interchanging occurrences in given strata as the local conditions of temperature vary, as in proximity to intrusives. For this reason, the aluminum silicate minerals are

often used to identify parameters of metamorphic intensity. Sillimanite, although common, seldom occurs as potentially exploitable crystals. The typical mode is often called fibrolite, which is a felty aggregate of extremely fine whiskers of acicular sillimanite interlaced and interlocked with quartz, mica, and other minerals. Beneficiation is usually impossible. In some areas, the sillimanite occurs as nodules and buttons that have marginal potential, as in the Pelzer Area of South Carolina (Espenshade and Potter 1960).

In Hart County, Georgia, there is a northeasterly trending zone about 16 km long in which matchstick-like sillimanite occurs. Beneficiation tests showed that a limited production of sillimanite in the 35-mesh range could be accomplished. But the deposits are narrow and limited, and no existing market or incentive for production of sillimanite concentrates exists in the United States (Furcron and Teague 1945).

In 1991, the USGS reported that a 30-cm-wide vein of sillimanite in Namaqualand schist "might be economically mined on a small scale." The sillimanite vein is in the Bethanien District of Namibia, Africa (Murray 1991).

Massive Sillimanite. Massive sillimanite has been produced for many years from the state of Assam, India. The Assam deposits consist of huge segregations of sillimanite and corundum, commonly in intimate association and weighing several tons. Considerable hand effort is employed to recover the boulders in a form suitable for sawing to refractory shapes, particularly for the English glass industry. Production of sillimanite in 1988 was 15 kt (Potter 1988), and although exact production figures are vague, massive sillimanite production in this region was assumed to be the same in early 2005.

The most important deposits of massive sillimanite-corundum occur in the Republic of South Africa, in the Pella District near Pofadder, Namaqualand. Production reached a high of 46,184 t in 1963, but was down to 709 t in 1988 (Morgan 1990), and as of 2005, production had ended.

In the vicinity of Adelaide, South Australia, late-stage metasomatism resulted in a mixture of kaolin and included boulders and nodules of sillimanite. The sillimanite is recovered as a by-product in the process of manufacturing refractory clays. Other deposits of residual boulders of massive sillimanite have been exploited in this region. Beneficiation has been tried with some success on the sillimanite itself and on the by-products that are too low in grade to use directly. The Australian domestic market for such concentrates is limited, however, and as of 1988, no large-scale production had been described; reported production in Australia in 1988 was 66 t of sillimanite and 6,598 t of kaolinized sillimanite (Potter 1988). Although exact production estimates are unclear, it was assumed in early 2005 that production had ceased.

TECHNOLOGY

Exploration and Evaluation

Kyanite and its related aluminum silicate minerals have a relatively low value-to-weight ratio. Because they must be delivered to the consuming areas at competitive prices, an important preliminary consideration in any exploration project is the prospective cost of delivering the minerals to the market. Current freight charges range from \$20/t to \$80/t and vary greatly, depending on finite factors such as distance and fluctuating factors such as fuel costs. Kyanite is produced almost exclusively in Virginia and is therefore consumed mainly in the United States—or in the highly developed and industrialized countries of Europe and Japan that can be easily reached by ocean vessels sailing from the mid-Atlantic states. A similar pattern

exists with andalusite, where consumption is concentrated in South Africa and those parts of England, France, and Germany where the producers of refractories are concentrated.

A salable product must also be produced. Consumers become very accustomed to specific raw materials that have historically been used in the manufacture of their refractory products. Any deviation from the commonly accepted specifications imposes a considerable burden on products attempting to enter the market. When evaluating a prospect, one of the most important considerations in this regard is the liberation size of the crystals. This is especially true for kyanite, where the size of the kyanite particles has a direct impact on the expansionary characteristics of the material when fired. There are some attractive kyanite-quartzite deposits in the western United States, but the material cannot be beneficiated to the required specifications without grinding the ore to around 200 mesh, which is quite fine considering that most existing kyanite production is in concentrates in the size range of -28 to +35 mesh.

After initial investigation has indicated that both freight cost and the quality of the product can be competitive, normal techniques of surface sampling, geologic mapping, trenching, and diamond drilling are used to determine the quality of potential reserves. Because the kyanite deposits are produced by regional metamorphism, their composition is fairly consistent, although there may be variation of grade in zones. A pilot-plant production of the material would be the next step to determine if a salable product could be produced economically. It is important to produce, by reproducible pilot-plant techniques, a quantity of concentrates from a representative selection of ores sufficient to permit prospective consumers to test the new material extensively in their plants; there is no laboratory substitute for this kind of testing. Prospective producers of aluminum silicates have found, in many cases, that consumers may not be willing to use material from a new area. Competitive testing and specific approval is the only sure way that the marketability of a given kyanite product can be assumed.

Mining and Processing

Kyanite

In the United States, for most of the last 60 years, kyanite concentrates have been produced by flotation and magnetic separation. The two kyanite-quartzite deposits currently being mined (at Willis Mountain and East Ridge in Virginia) are monadnock features whose resistant ridges are exposed with little or no overburden. The deposits lie on the opposing limbs of the Whispering Creek anticline. Minerals other than quartz and kyanite associated with the deposit include muscovite, pyrite, rutile, topaz, magnetite, feldspar, and apatite. The rare mineral trolleite $[\text{Al}_4(\text{PO}_4)_3(\text{OH})_3]$, a hydrous aluminum phosphate, has also been noted in the kyanite quartzite (Giannini, Penick, and Fordham 1986).

The kyanite quartzite is drilled and blasted; secondary breaking is sometimes done with a hydraulic hammer. The ore is picked up with diesel-powered shovels, loaded in to trucks (up to 54.5-t loads), and hauled to the primary (jaw) crusher. At the primary crusher, the ore is reduced to -4 cm and passed by conveyor belt to the rod mill, which is in a closed circuit with a classifier, to grind the ore to -20 mesh. Water is added that creates a slurry from which the -200 mesh is removed (deslimed). The new slurry is conditioned with several ingredients and passed through a series of flotation cells that remove the pyrite and micaceous contaminants from the slurry. Tailings from the pyrite circuit are again deslimed and conditioned with other reagents and passed through a section of rougher flotation cells. The rougher concentrate goes to a two-stage recleaning circuit; tails of the rougher circuit go to waste.

The flotation concentrate consists of about 91% kyanite and 2% to 5% iron oxides, and the balance is quartz. The concentrates are dewatered by draining in open stockpiles or in drainage silos and are subsequently conveyed to a dryer where the moisture is reduced from almost 8% to near 0%. A reducing roasting technique in a rotary kiln elevates the temperature during the drying process to 482°C, followed by cooling in an oxygen-deficient atmosphere to render the iron oxide highly magnetic; ferric iron (Fe_2O_3) is converted to ferrous iron (Fe_3O_4). The dried concentrates are passed over a series of high-intensity and low-intensity magnetic separators, which reduce the iron content of the product to less than 1%. The result is a raw 35-mesh kyanite product, ready for shipment. Five mesh sizes (35, 48, 100, 200, and 325) are available. A typical analysis of the product is as follows:

Al_2O_3	57%
SiO_2	38%
Fe_2O_3	0.6%
TiO_2	0.8%

The magnetite is stockpiled, with no current market available, and pyrite tails are sold for use in the production of sulfur and as micronutrients in the fertilizer industry. The by-product quartz is marketed for golf courses, sand blasting media, masonry, and concrete sand, as well as for other applications.

Kyanite deposits of India have traditionally been exploited by labor-intensive techniques. In the beginning, it was sufficient to simply gather the cobbles and boulders of kyanite that had been exposed by weathering. Later, primitive mining methods were initiated and the large segregations were drilled, blasted, and hand cobbled in preparation for shipment. Dozens of these small operations employed numerous people. As time passed and the availability of readily hand-picked material decreased, the beneficiation methods became more sophisticated. The picking belt is still an important beneficiation technique, however. High-grade kyanite nodules, and those with segregation too low in grade to be shipped directly, are now crushed and subjected to more sophisticated beneficiation techniques, including flotation and magnetic separation. Currently, there are no large-scale integrated beneficiation plants in India of the kind employed in the United States.

Andalusite

In the Republic of South Africa, andalusite sands in the Marico District of the Transvaal are beneficiated with heavy media separators and high-intensity magnetic separators. A typical analysis of the product follows:

Al_2O_3	52% to 57%
SiO_2	35% to 44%
Fe_2O_3	1% to 4.5%
TiO_2	0.04% to 4%

In France, DAMREC produces andalusite concentrates near Glomel in Brittany. The black andalusite schist contains about 20% coarse euhedral andalusite porphyroblasts. The crystals are about the diameter of matchsticks and range from 1.9 to 2.5 cm in length. The schist is deeply weathered and friable to at least a depth of 9.1 m. The ore is drilled with a wagon drill, blasted, and transported with a rubber-tired front-end loader with a 2.29-m to 2.74-m bucket. It is fed into a surge hopper through a 20.3 × 20.3 cm grizzly and discharged onto a 61-cm conveyor belt by a reciprocating feeder. Oversized material is reduced by hand with a sledgehammer to pass the 20.3-cm grizzly.

The conveyor belt carries the broken ore about 45.7 m to an autogenous mill, which consists of a drum, 4.6 m in diameter, revolving on eight truck tires. This mill reduces the ore to 100% -0.3 cm before it travels to the furnace, which is air-swept with heated air in closed circuit with two air classifiers. The sized ore is fed into a hopper, from which it is passed over a four-roll high-intensity magnetic separator. The nonmagnetic fraction is conveyed to the heavy-media separator, and the magnetic particles are discarded.

The heavy-media separator circuit consists of a hopper in which the andalusite ore is blended with ferrosilicon slurry and then pumped through a hydrocyclone. The specific gravity of the slurry is controlled automatically by a water-metering device ahead of the blending hopper. The first stage of the two-stage heavy-media separator circuit is controlled at a specific gravity of about 2.3. The final effective specific gravity is adjusted by regulating the velocity of the slurry through the cyclone. The second stage is controlled in a similar fashion. The heavy (sink) product from the heavy-media separator is screened at about 35 mesh to recover the ferrosilicon media. The finished andalusite product consists of dark brown to black, roughly equidimensional grains ranging in size from -8 mesh to $+35$ mesh, and contains about 59.2% Al_2O_3 and 1.0% Fe_2O_3 .

In 1988, the Council for Mineral Technology (Mintek) published a review on the development of the andalusite industry in the Republic of South Africa. The publication discussed Mintek's role in early beneficiation methods and techniques developed since 1962; Mintek was also instrumental in introducing heavy medium separation as a standard beneficiation operation. The report also discusses treatment of both hard shales and andalusite fines (Potter 1988).

Sillimanite

Segregations of sillimanite-corundum rock occur in the Pellar District in the northwestern part of Cape Province, South Africa. They have been produced for many years using labor-intensive techniques similar to those employed in India.

Synthetic Mullite

Synthetic mullite results from four main heating processes: (1) melting of alumina and silica or bauxite and kaolin in an electric furnace at $1,914^\circ\text{C}$; (2) sintering alumina and kaolin, bauxite and kaolin, or alumina, kaolin, and kyanite above $1,763^\circ\text{C}$; (3) calcining kyanite at $1,300^\circ\text{C}$; or (4) sintering a siliceous bauxite or mixtures of bauxite and kaolin at about $1,561^\circ\text{C}$. U.S. production of synthetic mullite in 2003 was estimated to be 322,050 t.

C-E Minerals produces three grades of synthetic mullite of varying alumina content by sintering bauxite with kaolin in its two plants. The company mines bauxitic kaolin from pits in Sumter County, near Andersonville, and also from properties near Eufaula, Alabama. Washington Mills Electro Minerals Corporation produces standard and electric grades of synthetic mullite by fusing alumina and glass-grade silica. The company also produces a zirconium mullite that offers better resistance to the thermal shock for ceramic products.

The three grades of synthetic mullite produced by C-E Minerals are Mulcoa 47, which contains 47% alumina produced from the kaolin component of the ore; Mulcoa 60, which contains 60% alumina produced from the bauxitic kaolin; and Mulcoa 70, which contains 70% alumina produced from the bauxite lenses. (Mulcoa 47 is not, for the purposes of this chapter, considered a true mullite because its alumina content is well below the 60% threshold of theoretical mullite.) C-E Minerals' Georgia plants have a total capacity of 452,529 tpy. Five kilns were in operation in 2003.

Kyanite Mining Corporation's mullite plant has the capacity to produce 27,216 tpy of its calcined kyanite; a number that will soon be increased to 36,287 tpy as the company installs more efficient pollution controls. It is estimated that with the addition of a new product line of lightweight aggregates, production could easily reach 40,000 tpy by 2006.

USES

Although the three minerals that comprise the sillimanite group have different properties, they are all used primarily as raw materials in the manufacture of heat-resistant refractory ceramics. As such, the demand for each is driven largely by the health of the steel and foundry industries, and the changes in technology that affect the usage of refractories in those industries.

Today it is estimated that 70% of the kyanite output is used in refractories: 55% for smelting and processing of ferrous metals, 10% for nonferrous metals, and 5% for glassmaking and ceramics. The remaining 30% is used for other industrial ceramic applications such as investment casting, kiln furniture, and railroad friction products, among others.

The main uses of kyanite are in high-temperature (refractory) cements/mortars, ramming mixes, and castables. With clay or other ingredients, the kyanite is used in firebrick, insulating brick (brick for rotary kilns and furnaces), and in abrasive and other kiln furniture. The expansion characteristics of kyanite are valuable because they offset shrinkage of other ingredients and produce a stable refractory body. When calcined, kyanite increases in volume by 16% to 18%, compared to only about 4% and 6% for sillimanite and andalusite, respectively. Thus, when fired in a refractory mortar containing shrinkable components such as clays, kyanite will expand to form a tight lock in a furnace or kiln. Finely ground kyanite, in the 200-mesh range, is used in body mixes for sanitary porcelains, wall tile, casting molds, and special purpose ceramics where the expansion characteristics of kyanite are advantageous.

An even greater proportion of andalusite is consumed by the refractories industry—possibly up to 80%. Andalusite, which can be sold in much larger sized particles than kyanite because of the beneficiation processes involved and the mineral's lack of expansionary characteristics, is mainly used by refractory companies as the aggregate component in bricks and other precast shaped products. It has very good creep-resistant and load-bearing properties.

The largest market for sillimanite minerals is in the manufacture of refractory products, mainly for the iron and steel and nonferrous metal smelting industry.

All the sillimanite minerals convert to mullite (about 88%) and silica (about 12%) when heated to temperatures ranging from $1,250^\circ\text{C}$ to $1,500^\circ\text{C}$. Each of the minerals converts to mullite at a different temperature, with kyanite needing the least heat and sillimanite the most. Mullite is extremely refractory, has a small coefficient of thermal expansion, and is resistant to abrasion and slag. Because mullite is the mineral component that is sought after by refractory engineers, the sillimanite minerals could theoretically be regarded as mullite ore.

The addition of mullite to refractory and porcelain bodies will increase the fired strength as a result of the interlocking of mullite's long, needlelike crystals. Mullite's addition will also increase resistance to deformation under load, increase dielectric properties at both normal and high temperatures, and increase thermal resistivity. Mullite also decreases the coefficient of expansion, promotes a uniform rate of such thermal expansion, and reduces refractory and porcelain bodies' tendency to spall. The mullite produced in Virginia by Kyanite Mining Corporation and the synthetic mullites

produced from kaolin in Georgia are used for traditional refractory applications such as bricks, monolithics, and castables, as well as in the investment casting industry for stuccos and slurry coats. Ceramic uses of mullite include kiln furniture, hot-zone and car-top decks of tunnel kilns, and rollers for roller kilns. Mullite porcelains are used in spark plugs and laboratory-ware applications.

ECONOMIC FACTORS

Prices

Kyanite, free on board (f.o.b.) the plant in Virginia, is \$149 to \$196/t, and calcined kyanite (mullite) is \$248 to \$295/t on the same basis. The price of andalusite, f.o.b. Transvaal, South Africa, ranges up to \$286/t. Synthetic mullite is \$220 to \$1,320/t, depending on grade and type.

Reserves

Cooper (1965) noted that reserves of kyanite-bearing quartzose rock containing 10% to 30% kyanite in the United States were reported at about 82.5 Mt. Since that time, the only appreciable deductions from the 1965 estimate have been Kyanite Mining Corporation's extractions at the Willis Mountain and East Ridge mine sites in Virginia. In 1949, a USBM drilling program on Willis Mountain (Virginia) indicated that 53.6 Mt of 2.5% kyanite were exploitable by open-pit mining (Jones and Eiletsen 1954), and potential reserves were much larger. Over the course of the last half century, Kyanite Mining Corporation's activities at the Willis Mountain site have reduced reserves to roughly 47.6 Mt. Reserves of the East Ridge deposit, 8 km distant, are not included in this figure. Other deposits in Virginia include Woods Mountain in Buckingham County, as well as properties to the south in Prince Edward County. At an annual mining rate of 329,885 to 412,357 t of ore, the deposits of kyanite in Virginia are adequate for many years. At Graves Mountain, Georgia, where the deposit is no longer mined, previous geologic mapping and diamond drilling indicated a reserve of 24.7 Mt of 25% ore. In the Van Noy (1970) study of Goat Mountain and Woodrat Mountain, near Kamiah, Idaho, hundreds of millions of metric tons of 25% aluminum silicate ore were available for open-cut mining. Remoteness from major markets and the difficulty of beneficiation, however, have stalled development. If the schists and gneisses, which contain approximately 10% kyanite, are noted as resources in North America, the resource potential is probably very large and indeed may not even be recognized or discovered yet (Potter 1985).

According to the Minerals Bureau of South Africa, reserves of andalusite and sillimanite are 94.9 Mt. Kyanite reserves in Brazil are given at about 2.4 Mt. Andalusite occurs in France where reserves of andalusite content amount to about 2.4 Mt. Sillimanite deposits are located in Australia, India, and Russia (Potter 1985).

GOVERNMENT CONSIDERATION

Depletion allowance rates of 22% for domestic production of kyanite were unchanged through 2004.

From August 23, 1951, through March 4, 1970, the eligibility for stockpiling of lots of kyanite ore and concentrates, or of fused synthetic mullite, was determined according to criteria in the National Stockpile Purchase Specification P-27-R (February 29, 1960, superseding issue of August 23, 1951). The statement listed as chemically acceptable three types of kyanite if they contained not less than 59% alumina; not more than 39% silica; and not more than specified proportions of iron, titanium, lime, magnesia, alkalis, and total fluxes. Chemical requirements for fused synthetic mullite called for alumina within a range of 75% to 80%, silica 20% to 25%, and total impurities not exceeding 1%. Additionally,

both kyanite and mullite for stockpiling were required to conform to a catalog of specific physical properties and pyrometric cone equivalent ratings. Currently, sales of kyanite-group minerals are based on bargaining of the consumer and the seller. Chemical analyses, physical characteristics, and required service testing are usually not available. The stockpile of lump kyanite in September 1990 was 90.7 t; 783.4 t of nonstrategic-grade material were also retained in government stockpiles. As of early 2005, the government had sold its stockpile of lump kyanite.

FUTURE TRENDS

The overall use of sillimanite group minerals has increased slowly but steadily throughout the world over the last few decades—although there was a marked downturn in consumption of these minerals during the first few years of the new century. This downturn was primarily caused by overcapacity problems in the worldwide steel industry, especially in the United States and Europe. These problems seem to have dissipated as of late 2003 and early 2004, resulting from bankruptcies, plant closings, and mergers and acquisitions in the United States and Europe combined with a surge of economic growth in China and other Asian economies that stoked global demand for steel just when supply was being cut. This Asian-led economic growth has also driven up the price for almost all raw materials—many of which are partially or wholly competitive with one or more of the sillimanite minerals. For example, the quickly rising price of zircon and alumina has led to an increased use of mullite as a direct substitute in many refractory and investment casting applications.

There are, however, countervailing trends that could suppress demand—especially for andalusite. As steel companies continue to become more efficient and cost conscious, they are making strides to consume fewer pounds of refractory per ton of steel that they produce. In addition, more and more of the world's steel—especially in Europe and the United States—is being produced in electric arc furnaces from scrap metal. This kind of steelmaking process relies more heavily on refractory monolithic instead of refractory bricks. Because a large proportion of an alusite is used in making refractory bricks, the future growth prospects for that particular sillimanite mineral are difficult to discern.

Overall, however, demand for sillimanite minerals is likely to continue to grow slowly—but possibly not as steadily as it has in the past. A forecast for demand of kyanite, andalusite, sillimanite, and synthetic mullite in 2010 may be in the range of 700,000 to 770,000 t.

Lime

Stanley T. Krukowski

INTRODUCTION

Lime, or calcium oxide (CaO), is known as one of the most versatile chemicals, and its manufacture and use is fundamental to society. Throughout history, civilization worldwide has relied on the use of lime. Because of the universal and fundamental nature of the global lime industry, this chapter focuses on lime production and use in the United States as representative.

A manufactured chemical product resulting from the calcination of limestone in its various forms, lime's major mineral component—calcium carbonate (CaCO₃)—is dissociated by the application of thermal energy, producing CaO and CO₂. When water is added, it is commonly known as *hydrated lime*, or *slaked lime* (Ca(OH)₂). Almost 40 different lime products are available, a fact that contributes to confusion and misunderstanding over the use of the term *lime*. Frequently, the word is used erroneously to denote almost any kind of calcareous material, including finely ground limestone and/or dolomite.

Lime is made from high calcium, or magnesium (or dolomitic) limestone and dolomite that has a minimum of 97% total carbonate composition. Normally, high calcium lime (quicklime) contains less than 5% MgO; the balance is CaO. When lime is produced from high-magnesium limestone (dolomite, CaMg(CO₃)₂), the product is referred to as dolomitic lime (dolomitic quicklime, or refractory dead-burned dolomite, CaO•MgO) and contains more than 35% MgO; the remaining balance is CaO. Magnesium lime, produced from magnesium limestone (also referred to as dolomitic limestone), contains between 5% and 35% MgO. Other typical lime products include high-calcium hydrated lime (calcium hydroxide, Ca(OH)₂), dolomitic hydrate Type N (Ca(OH)₂•MgO), and dolomitic hydrate Type S (Ca(OH)₂•Mg(OH)₂).

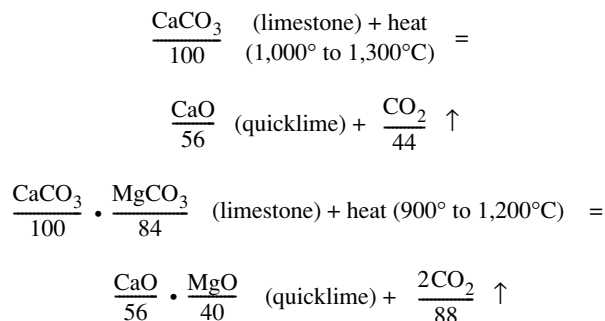

Calcination/Hydration

The major process in the production of lime, calcination refers to a broad class of reactions in which a substance is heated so that a chemical or physical change takes place. In the case of the limestone/lime reaction, limestone is heated to less than its melting point, resulting in the dissociation of calcium carbonate into calcium oxide and carbon dioxide.

The manufacture of lime probably was known in prehistoric times and certainly was well known in the ancient world. Any basic understanding of calcination most likely had its origins in the earliest days of alchemy; the general reaction class was identified in an

Arabic text printed in 1000 AD. It was not until the mid-1700s to the mid-1800s, however, that this basic reaction became understood from a scientific perspective. The production of lime is so basic and simple that its underlying scientific principles received only intermittent investigation over the years. Instead, most thinking on the subject was directed toward the development of kilns. Only in the last 40 years or so, as a consequence of kiln studies (particularly those focusing on energy consumption and fuel efficiency), has lime received any concentrated scientific investigation relative to thermodynamics and kinetics of calcination and hydration reactions.

In the calcination of limestone, the basic chemical reaction is as follows:

There is nearly universal agreement about equilibrium conditions related to this limestone/lime reaction, and many different calcination models were developed for the reaction. The model in Figure 1 shows that calcination is a function of both temperature and CO₂ pressure. It provides no indication of the rate at which the reaction takes place.

Because calcination reaction starts on the exterior surface of limestone particles, then proceeds toward the center, calcination is strongly time variant with different limestones. As calcination progresses, CO₂ is released at the limestone/lime (CaCO₃/CaO) interface and must pass through the lime to exit at its exterior surface. Because calcination is limited by diffusion of CO₂ gas to the surface of partially calcined limestone, the following factors all play a significant role in rate of calcination:

- Natural impurities in the stone
- Differences in crystallinity
- Grain boundary chemistry

NOTE: Conditions below the curve cause the reaction to go toward lime (CaO), while above the curve the reaction proceeds toward calcite. Only on the curve is the equilibrium maintained and the reaction does not proceed in either direction. Most lime kilns have production bed temperatures of 1,000°C to 1,150°C.

* The values given in this range do not necessarily represent minima and maxima percentages.

- Density variations
- Imperfections in the crystal lattice

Therefore, only after completing adequate burn tests designed to evaluate a given limestone is it determined suitable. In coal-fired kilns, the process of calcination is even more complex when additional chemical substances are introduced into the calcination environment. The reader is referred to Boynton (1980), Oates (1998), and Beach et al. (2000) for more detailed descriptions of the complete calcination reaction and the inherent differences among kiln systems.

CO₂ is released during calcination of high calcium limestone, resulting in a 44% weight loss when the reaction is complete, or a 48% weight loss for a highly dolomitic limestone. The trade term for this weight percent reduction is *loss on ignition* (LOI) and is frequently used to measure the completeness of calcination.

Because the calcination reaction is chemically reversible, *quicklime* or *burnt lime* is frequently referred to as being highly reactive, or unstable. The more stable form of lime, *hydrated lime*, is commonly preferred and specified by the consumer. Hydrated

lime is obtained by adding water to quicklime to produce a dry, fine powder. The affinity of quicklime for moisture is then satisfied, but it still retains a strong affinity for CO₂.

Hydration is the combining of calcium oxide with water in a reversible reaction to form calcium hydroxide:

The reaction is exothermic; the accepted value for the heat of hydration is 15.456 kcal/g mol of CaO. This is actually a three-step reaction; the first is the dissociation of CaO into a Ca⁺⁺ ion and O⁼ ion:

Secondly, the water ionizes into two hydroxyl ions because of the strong attraction that the oxygen anion exerts on the water molecule:

Finally, calcium and hydroxyl ions combine to form calcium hydroxide:

Because this reaction is reversible, the hydrated lime may revert to the original oxide form when heated.

Chemical Properties

The success of calcination is measured by the available CaO content of the lime. In the case of dolomitic lime, this is expressed as total oxides. *Total lime* refers to the amount of calcium present in lime. *Available lime* is a measure of the amount of CaO in lime; that is, the amount available to combine with water to form calcium hydroxide. It is, in effect, a measure of the purity of the lime. Available lime is typically 3% to 5% less than total lime, because some calcium is uncalcined and remains as limestone core or has combined with other impurities in the kiln to form various oxides. Typical chemical analyses of commercial quicklimes are presented in Table 1. The purity of the limestone feed is the major factor influencing the purity of lime, followed by its manufacture. The major impurities are silica, iron, alumina, and sulfur. During calcination these impurities react with some of the calcium oxide, reducing the available lime by forming a variety of minerals such as silicates, aluminates, and ferrites. Consequently, even the purest high-calcium limes assay less than 95% in available lime, usually several percentage points less than total oxide content.

Reactivity of quicklime is the measure of the rate at which CaO will react with water, or the rate of release of the heat of hydration. The heat of hydration, or slaking, is the amount of heat liberated when quicklime reacts with water (1,140 kJ/kg of CaO). Impurities and uncalcined limestone core affect hydration by decreasing the amount of total lime. As an example, sulfur in the form of calcium sulfate inhibits hydration out of all proportion to its actual weight percent concentration, perhaps more than 100 times (Boynton 1980). If dolomite is present in the stone feed, it also can inhibit hydration, resulting in a slower reaction—nearly three orders of magnitude slower than that of calcium oxide. Early in the hydration reaction, dolomite appears practically inert but, given sufficient time, it will hydrate. The heat of reaction is nearly the same as for calcium oxide, but the time necessary for complete hydration to occur may be hours. Complete hydration of calcium oxide occurs in seconds. Only 2% to 5% magnesium oxide present in quicklime may render it unsuitable for many applications; however, when quicklime is used in steel-making, MgO is not considered an impurity.

Quicklime has a high affinity for water. After partial hydration, it also has a high affinity for carbon dioxide. The affinity for water causes quicklime to air slake, which may reduce its reactivity significantly. A reduction in reactivity also occurs when slightly

hydrated lime combines with low levels of carbon dioxide to form calcium carbonate.

Fuel such as coal also may contribute to the total amount of impurities in the lime product. Silica, alumina, iron, and sulfur are the main contaminants in this case also, but the finer fraction of run-of-kiln tends to have a higher content of these impurities. Trace elements such as lead, arsenic, molybdenum, and chromium, to name a few, may be considered toxic, making quicklime unsuitable for some applications (e.g., treatment of drinking water).

On slaking into a slurry, or milk-of-lime, the saturated solution ionizes immediately into Ca^{++} , Mg^{++} , and OH^- ions, creating one of the strongest bases. Even a trace of lime will yield a pH of 11.2 and up to nearly pH 13 at saturated solution and low temperature.

Unlike other strong bases such as NaOH and KOH, $\text{Ca}(\text{OH})_2$ and $\text{Mg}(\text{OH})_2$ are diacid bases. Therefore, one molecule of lime will neutralize two molecules of acid (sulfuric, hydrochloric, etc.). For example, at equal weights, CaO has 30% more neutralizing power than caustic soda (sodium hydroxide). Dolomitic quicklime has 16% greater neutralizing power than pure CaO because of its MgO content.

Major impurities in hydrated lime include calcium carbonate, calcium oxide, and magnesium oxide. Silica, alumina, iron oxide, and calcium sulfate (CaSO_4) are minor impurities that can influence the intended use of hydrated lime. High levels of toxic trace elements (such as lead, antimony, arsenic, cadmium, and chromium, to mention a few) can prevent the use of hydrated lime in specific applications (e.g., potable water treatment, foodstuffs, and pharmaceuticals).

The reader is referred to works by Boynton (1980) and Oates (1998) for excellent discussions on the chemical properties of quicklime and hydrated quicklime.

Physical Properties

Important physical properties of lime are listed in Table 2. Lime is typically white with varying intensities of brightness, although, depending on the presence of particular impurities, it may have a light cream, buff, or gray cast. Lime has either no odor or a slightly earthy odor. Although its texture is earthy, appearing amorphous, lime is actually microcrystalline. Both calcium oxide and magnesium oxide have cubic crystal structures.

Porosity of commercial quicklime is dependent, in part, on the original porosity of the limestone and on the decomposition process in the kiln. The severity of calcination (time and temperature) affects both the porosity and chemical reactivity of lime. When lime is *soft-burned* (lightly sintered and calcined at relatively low temperatures, 900° to 1,200°C), very little or no shrinkage occurs, and a porous, softer, very reactive lime is produced. Lightly burned lime can have porosities up to 55% by volume.

When lime is *hard-burned* (sintered at relatively high temperatures, 1,300° to 1,600°C and overburned), a denser (porosities typically below 25%), physically stronger, less reactive lime is the result. In either case, the lime will readily hydrate in water, although the rapidity of hydration is much greater with soft-burned lime than with hard-burned lime. Boynton (1980) and Oates (1998) present excellent discussions of the physical properties of both soft- and hard-burned lime.

In either case, the heat of hydration is appreciable: 1,134 kJ/kg and 886 kJ/kg of quicklime for high calcium and dolomitic types, respectively. This strong exothermic reaction will boil water easily and, under certain hydration conditions, temperatures of 290° to 315°C have been reached, causing dehydration of the freshly slaked lime. Quicklime can be so reactive that it will explode on contact with water. Associated with the reaction of quicklime with water is a corresponding increase of 2.5 times its original volume.

Table 2. Properties of typical commercial lime products

Quicklimes		
	High Calcium	Dolomitic
Primary constituents	CaO	CaO and MgO
Specific gravity	3.2–3.4	3.2–3.4
Bulk density (pebble lime), g/cm ³	0.88–0.95	0.88–0.96

Angle of repose*	55°	55°
Hydrates		
	High Calcium	Dolomitic
Primary constituents	$\text{Ca}(\text{OH})_2$	$\text{Ca}(\text{OH})_2$ + MgO
Specific gravity	2.3–2.4	2.7–2.9
Bulk density, g/cm ³	0.4–0.56†	0.4–0.56
Specific heat at 38°C, kJ/kg	0.62	0.62
Angle of repose*	70°	70°

Adapted from National Lime Association 1999.

* The angle of repose for both types of lime (hydrate in particular) varies considerably with mesh, moisture content, degree of aeration, and physical characteristics of the lime (e.g., for quicklime it generally varies from 10° to 13°C and for hydrated lime it may range as much as 2° to 26°C).

† In some instances, these values may be extended. The Scott method is used for determining the density values. In calculating bin volumes, the lower figure should be used.

Although limestone is almost totally insoluble, lime is slightly soluble in water in the range of 0.54 to 1.4 mg/L, depending on the temperature. As water temperature rises, the solubility of lime diminishes. The addition of sugar will increase these solubility values by many times.

The reader is referred to works by Boynton (1980) and Oates (1998) for excellent discussions on the physical properties of quicklime and hydrated quicklime.

HISTORY

Lime is one of the oldest chemicals known to humans. It was probably discovered in prehistoric times when limestone, which was used in the construction of fireplaces and hearths, broke down into its molecular constituents. Air slaking or hydration by rainwater produced a simple type of putty that prehistoric humans put to use principally as a binding agent.

Evidence from eastern Turkey revealed that lime mortar was used in terrazzo floors at an archaeological site dated from 7,000 to 14,000 years before the present (BP). Firm evidence exists for the early use of lime from 8,000 years BP in the Near East, as well as in the Balkans where lime mortar was used in the construction of a floor; the mortar was a combination of lime, sand, clay, and water. The ancient Egyptians used lime for plaster in the construction of the pyramids, while the Chinese added lime to mortar for the Great Wall; 5,000 years ago in Tibet, lime served to stabilize soil. Other ancient civilizations that used lime for various applications include the Greeks, Romans, Incans, Mexicans, and Mogul Indians. Several ancient texts mention the production and use of lime (e.g., the Bible, and the writings of Cato the Elder and Pliny the Elder).

A lime kiln was excavated in Mesopotamia and dated at about 2450 BC. Many ancient lime kilns are known from Roman archaeological sites, including army legion encampments throughout Europe. The Romans were probably the most innovative in the production and use of lime. They developed the technology of lime burning and experimented with an d further

developed the use of hydraulic lime, pozzolanic lime cements, lime mortars, and concrete. The formula for hydraulic lime cement was lost in time but rediscovered in 1756 when John Smeaton, a British engineer, patented it.

Lime was employed in the ancient world in a variety of processes including bleaching fabric, tanning hides, agricultural soil amending, glassmaking, painting (whitewashing), and in making putties and glues when combined with certain organic or inorganic substances. Aboriginal people as well as ancient Roman physicians used lime in different medical treatments. Well into the 20th century, lime was used most extensively in the building trades as the major constituent in mortars, plasters, and cements.

Little is known about lime chemical processes and technology during the Middle Ages, although alchemists began to wonder about and to study the phenomenon of calcination. An Arabic text printed in 1000 AD identified and addressed the general type of reaction responsible for calcination. Lime was widely produced and used during medieval times, however, and that knowledge is reflected in the writings of the day.

From 1750 to 1752, Joseph Black, M.D., studied and first described the calcination reaction of "magnesia alba," which consequently led to the discovery of carbon dioxide. In 1766, De Ramecourt published a treatise on the art of the lime burner, which detailed the design, operation, and economics of limestone quarrying and lime burning. Many treatises and books were written throughout the 19th century and into the early 20th century on the subject of lime production by, for example, Searle (1935), Vicat (1995), and Cowper (1998).

Up to the 20th century, lime kiln design was relatively simple. The easiest method of production was to dig a shallow pit, fill it with firewood and limestone, and set it ablaze. Lime produced in this manner most often was used locally for construction and agricultural purposes. Since ancient times, kilns were either a beehive oven design or a simple vertical shaft kiln. The former also was used for charcoal and coke production, while the latter produced lime in relative abundance, mostly for the building trades. Limestone was quarried from a local deposit, and softball-size stone was placed in the shaft with alternating layers of firewood. The fuel and limestone burned for several days. When the fire stopped and the kiln cooled to an appropriate temperature, the lime was removed out of the shaft from the draft tunnel at the bottom of the kiln. The product was then shipped in baskets or barrels to the work site. Some kiln designs allowed the continual addition of fuel and stone at the top of the shaft; the mixture burned in the shaft below, and the lime was drawn out at the bottom. Today, the manufacture of lime is more complicated and is explained in the next section.

PRODUCTION AND TRADE; RESOURCES AND RESERVES

U.S. Production

In 2003, the U.S. Geological Survey (USGS) reported that the United States produced 19.2 Mt of lime, an increase of 1.3 Mt (a 7.2% increase) compared with 2002 (Table 3). The value of lime sold or used was \$1.24 billion (Miller 2003). Production figures represent the total lime sold or used by domestic producers, including the commercial sale or captive consumption of quicklime, hydrated lime, and dead-burned refractory dolomite.

In 2003, 76 plants in the United States produced high-calcium quicklime, and 23 plants produced dolomitic quicklime. High-calcium hydrated lime was produced at 40 facilities, and dolomitic hydrated lime was produced at 7 facilities; most hydrators are located at lime plants and usually do not occur as stand-alone facilities. Ninety-six plants in 32 states and Puerto Rico made some type of lime product in 2003 (Table 4). Principal lime-producing states in 2003, in descending order of production, were Missouri, Ala-

bama, Kentucky, Ohio, Texas, and Pennsylvania. The top 10 companies, in descending order of production, were Carmeuse Lime, Chemical Lime Co., Graymont Ltd., Mississippi Lime, Global Stone Corp., Martin Marietta Magnesia Specialties LLC, U.S. Lime & Minerals, Western Lime Corp., Southern Lime Co., and Ispat Inland Inc. These companies operated 43 lime plants (less than half the total number) and eight separate hydrating plants, accounting for 87% of the combined commercial sales of quicklime and hydrated lime and nearly 83% of total lime production.

U.S. Imports and Exports

The United States exports and imports quicklime, hydrated lime, hydraulic lime, and dolomitic lime. In 2003, the USGS reported that the U.S. exported 97,800 t (107,806 st) of lime valued at \$13.7 million; about 94% went to the United States' nearest neighbors, Canada (about 88%) and Mexico (6%); about 4% was exported to Germany; and the remaining 2% went to various other countries. The United States imported 202,000 t of lime (223,000 st) valued at \$22.5 million in 2003, with 63% from Canada, 36% from Mexico, and the remaining 1% from various countries (Miller 2003).

Because of its high place value and low-to-moderate unit value, most lime consumed in the United States is manufactured within its boundaries. Because most exports and imports (more than 94%) are traded with Canada and Mexico, U.S. export/import statistics also reflect this.

World Production

In 2003, 120 Mt of lime were produced on a worldwide basis (Miller 2003). In 1990, the Soviet Union had been the largest producer of lime, a position it held for many years. Its collapse, however, in 1991 changed the production statistics since each of the new republics in the Commonwealth of Independent States (CIS) report their own respective production figures. Only in 1998 did the USGS begin to list the production figures of CIS countries separately, and not all were accounted for. Traditionally, lime usage in the Eastern Bloc nations, including the former Soviet Union, was focused on steel production.

European production also is largely dedicated to steel production and generally is consumed within the European trading community. Within the European steel industry, there has been a move toward greater use of dolomitic lime as well as an increased use of powdered lime rather than pebble lime. Powdered lime is used in synthetic slag and ladle furnaces during secondary steelmaking.

Table 5 lists the production figures from various countries. Variations in quality and types of lime, production technologies, and industries manufacturing lime, plus the frequent confusion with limestone data, make accurate reporting of world lime information extremely difficult and certainly incomplete (Miller 2003). Except from a few industrialized nations, accurate lime data are difficult to obtain.

The largest producer of lime products is China, followed by the United States. The steel industry is the largest user of lime in the industrialized nations. Consequently, the large lime producers in Table 5 also produce large quantities of steel and reduced iron. These countries are Brazil, China, Germany, Japan, Russia, and the United States. Mexico also is a relatively large producer of lime, the vast majority of its production consumed in steelmaking. In developing countries, substantial amounts of lime continue to be used in the building trades and agricultural applications, such as soil amendments.

World Limestone Resources

About 20% of the earth's sedimentary crust is formed by limestone, which is distributed widely throughout the world and exists

in relative abundance on every continent. In virtually every country in the world, limestone resources are produced on a large scale (Harben 2002). Many limestones are remarkably pure and contain less than 5% noncarbonate impurities, so that even when employing primitive methods of calcination, it is possible to manufacture relatively high-purity lime products. The USGS reports that worldwide resources of limestone and dolomite are adequate for the production of lime (Miller 2003).

GEOLOGY

Mineralogy

The principal mineral constituent of limestone is calcite (CaCO_3), but it may also contain the minerals dolomite ($\text{CaMg}(\text{CO}_3)_2$), aragonite (CaCO_3), siderite (FeCO_3), ankerite ($\text{Ca}_2\text{MgFe}(\text{CO}_3)_4$), and magnesite (MgCO_3). Calcite and dolomite are in the hexagonal crystal system and have perfect rhombohedral cleavage; aragonite is in the orthorhombic crystal system. Calcite and aragonite can be distinguished from dolomite by their immediate effervescence in cold, dilute hydrochloric acid. Calcite and aragonite have a hardness of 3 on the Mohs scale, while dolomite is slightly harder at 3.5 to 4.0. Unless the limestone under examination is nearly monomin-

erallic, the distinction between calcitic and dolomitic limestones may be difficult in hand samples. Most limestones are mixtures of the previously mentioned minerals. High-calcium lime is produced from limestone with >95% CaCO_3 , and high magnesium dolomitic lime is produced from dolomite with 40% to 46% MgCO_3 ; however, a wide range of dolomitic lime products are manufactured with varying amounts of MgCO_3 .

Geology of Limestone

Limestone is the raw material from which lime is manufactured. In its broadest definition, limestone is any rock rich in CaCO_3 . Other cations (e.g., magnesium and ferrous iron) occurring in limestone may change the carbonate mineralogy of limestone as well as its physical characteristics, such as color, brightness, specific gravity, hardness, and tenacity. Limestone also is classified further by texture, origin, fabric, structure, and geology. Almost all limestone was biogenic during one phase of its formation and was deposited in every geologic time period. Chemically precipitated limestone deposits usually are small, with the exception of some travertine deposits.

Limestones generally were deposited under marine conditions in relatively shallow near-shore environments; less common are

deeper water marine deposits and freshwater lacustrine deposits. Deposits of limestone typically occur in layers or beds ranging from laminae (fractions of a millimeter in scale) to massive bedding (meters in scale). Although limestones usually occur as sedimentary rocks, marbles form when carbonate rocks are metamorphosed under intense heat and/or pressure, resulting in a coarsely crystalline, foliated, and monomineralic rock. For further reading, Oates (1998) presents a comprehensive discussion on the geology of limestone.

In the United States, high-purity limestone and dolomite are located mainly in the eastern and central parts of the country; however, their entire distribution is not well known. They represent only a small fraction of the total limestone and may occur in restricted areas. Much of the high-calcium limestone and high-purity dolomite occur in formations that are widespread and in minable thicknesses, and contain resources that are relatively large and are adequate for the manufacture of lime for the next several hundred years (Hubbard and Ericksen 1973).

Because limestone is so wide spread in time and space, large high-grade deposits are relatively ubiquitous. It is because of this that limestone reserves are considered adequate for the manufacture of lime on a worldwide basis.

TECHNOLOGY

Exploration Techniques

Reconnaissance Geology

Exploration for high-calcium limestone and dolomitic rock begins with a thorough review of geological survey publications, including geological maps. Most government geological surveys, whether at federal or state (or provincial) levels, have inventoried the limestone deposits within their jurisdictions. This information will help the geologist plan a field exploration program that begins with reconnaissance sampling and mapping. If the reconnaissance includes a preexisting quarry, channel sampling of the quarry wall is the most representative collecting technique. Chip intervals are samples the geologist collects along the ledges of limestone outcrop(s), vertically

or perpendicular to bedding. Care should be taken to flake or chop off any weathered rock surface, ensuring as fresh a sample as possible; all mud, or organic material (e.g., lichens), or soil also must be removed. It is important to construct a geologic map of the prospect, if only in a rudimentary manner, and to accurately plot the sample sites. These samples are sent to the laboratory for assay, and if they indicate high-grade limestone that is adequate for lime manufacture, a drilling program is planned next.

Drilling

Diamond core drilling gives the most representative picture of the limestone deposit. Many geologists plan a core-drilling program on a widely spaced grid to determine the size and boundaries of the limestone deposit. Attitude of bedding also influences the spacing and location of drill holes, as well as the direction or angle of the drill hole. This first phase of drilling will provide a skeletal framework to plan additional drilling with more tightly spaced drill holes, perhaps with rotary drilling, which is faster and less expensive. In either case, the geologist must accurately log the core or drill cut-

tings (along with the driller's logs) to interpret the down-hole geology. Accurate logging is necessary to correlate the geochemical assays with the subsurface geology.

Samples for geochemical testing are obtained by splitting the core, carefully maintaining sample integrity by washing off any foreign materials such as drill mud, and by including the entire length of core per sample interval. In North America, typical sample intervals for both core and drill cuttings from rotary drilling is 5 ft (1.52 m), but geologic considerations and drilling conditions may dictate the sample interval. In rotary drilling, it is important to maintain borehole integrity so that rock from above does not contaminate the sample cuttings downhole.

Geophysical Methods

Geophysical methods are varied and are used on a case-by-case basis; they usually are employed to locate and interpret geologic features. These methods range from simple aerial photography to gravity and radiometric surveys. The author, for example, has used aeromagnetic surveys to locate and define the boundaries of

high-calcium limestone deposits in heavily forested metavolcanic terranes. Most geophysical methods, however, are used to determine the nature and amount of overburden associated with a limestone deposit.

Evaluation of Limestone Deposits

Grade

The grade of the rock is the most critical part in evaluating a high-purity limestone deposit. Whatever the limits, this grade must be consistent throughout the deposit. For example, high-calcium limestone should have 95% or greater CaCO_3 , with less than 5% impurities (MgCO_3 , SiO_2 , Al_2O_3 , and Fe_2O_3). Variations in chemistry must be plotted and mapped to plan future exploration drilling and/or mine planning. Silica and alumina (as clays), along with iron pyrite and/or iron oxide finely disseminated throughout the stone and acting as fluxing agents, may increase sintering during calcination.

Decrepitation

Physical characteristics of limestone play an important role in evaluating a deposit. They determine how the limestone will behave during calcination and may determine the type of kiln in which to invest. A bulk sample (usually tens or hundreds of tons) test burned in a full-scale operation is the most desirable method; however, small pilot kilns for testing purposes also may give a close approximation. The latter is less expensive, involves smaller sample sizes, creates less environmental disturbance at the bulk sample site, and involves fewer personnel. Alternate testing methods consist of burning small quantities in a laboratory muffle furnace and evaluating the integrity of the lime product by some type of physical impact or buffeting. One laboratory refers to the “3-ft concrete” and “5-ft concrete” tests where a lime pebble of prescribed diameter is dropped from 3- and 5-ft heights, respectively, onto a concrete floor. The broken shards of lime are counted and recorded—the more desirable stone having fewer shards. Another test consists of rotating lime pebbles in a drum and measuring the size fractions of broken lime pebbles. These tests are rather qualitative and somewhat subjective because they depend on operator experience; however, over time and by testing large amounts of different limestones, an empirical and comparative database can be developed.

Certain physical characteristics in limestones may indicate a general disposition toward decrepitation during calcination; however, not all stones with these characteristics will decrepitate. Limestones that display the following attributes or conditions, alone or in combination, are prone to decrepitation: coarse crystallinity; friability; foliation (as in marble); excessive calcite veining; microfracturing; highly porous; and thinly bedded.

Infrastructure

Because of the cost of transportation, the value of most industrial minerals is dependent on their location. Lime has both high place value and relatively low unit price; therefore, proximity of limestone resources to railroads and highway systems is significant. The availability of electrical power, water, and natural gas pipeline (as a fuel source option) also is essential.

Of additional consequence is the disposition of the land where the deposit is located in terms of ownership, nearest neighbor(s), and zoning laws and/or regulations. In places where the government owns the resources or the land, there are usually incentives for mineral development with some restrictions and fees. For example, in the western United States, much of the land is administered by the U.S. Bureau of Land Management or the U.S. Forest Service. A prospector needs to stake a claim and pay administrative fees for

recording, usually on both federal and local levels. On land that is owned privately, the resources and/or land must be obtained through contractual agreement or outright purchase (e.g., in the eastern United States where most land is held in fee).

Because residents in rural areas tend to be scattered over large distances, a lime operation would not impose on them as much as in towns or suburban developments, where homes would be closer to the operation. In the case of the latter, provisions typically are made to mitigate the effects of quarry blasting, dust and emissions, and visual impacts. It is equally important to consult with the nearest neighbors about their attitudes toward mine development and plant operation. In cases concerning a boriginal people, the developer needs to address their cultural concerns. In areas where zoning ordinances mandate land use and mitigation of industrial impacts to the neighborhood, it is still a good practice to meet with neighbors and discuss the scope of the planned operation.

Mining

Details of stone preparation, which comprises surface quarrying or underground mining, crushing, and screening to produce kiln-size stone, are covered in the Limestone and Dolomite chapter of this book.

Open-pit methods with bench drilling and blasting are the preferred mining practices; however, if the resource is scarce and is of sufficiently high grade, underground mining may be economical.

The major concern in quarrying limestone for kiln feed, though, is the effort to maintain grade control. Standard quality-control practice in a high-calcium limestone quarry consists of chemical analyses of each blast hole to ensure product standards. In quarries where the beds are uniform in attitude (strike and dip and thickness) and grade, this is routine. In limestone deposits with a variable chemical profile, or whose sedimentary bedding is tilted or folded, the assay results from quarry blast holes must be carefully scrutinized. It may be necessary to stockpile stone of different grades for the purpose of blending so that the kiln feed is a uniform grade.

Faulting and/or fracturing (jointing) may concentrate deleterious materials such as silica, alumina, and iron compounds that blast-hole sampling may fail to detect. Therefore, it is necessary for the geologist or quarry manager to examine the quarry walls and conditions so that these potentially harmful materials can be avoided.

LIME MANUFACTURE

Production of lime typically involves three main processes: stone preparation, calcination, and hydration, although hydration is not necessary for several lime uses. The simplified flow diagram (Figure 2) outlines the various production steps. Details of stone preparation, which comprise surface quarrying or underground mining, crushing, and screening to produce kiln-size stone, are covered in the Limestone and Dolomite chapter. Because lime must meet certain chemical specifications, the various steps in stone production are controlled carefully to prevent contamination with impurities associated with the limestone deposit, particularly silica, alumina, and iron oxide. Sulfur and magnesium are other impurities with which some customers are concerned. Accordingly, many lime operations practice selective quarrying methods and also may wash limestone kiln feed.

Calcining

Although limestone calcining (or burning) is a relatively simple operation chemically, a wide variety of kiln systems are used today. These include vertical, rotary, rotary with preheaters, and multiple-shaft regenerative. This variety of production methods is in striking

contrast to the portland cement industry, which almost exclusively utilizes rotary kilns with preheaters.

The most important factors in selecting a lime kiln are the burning characteristics of the stone, fuel consumption, and capital equipment costs. Other factors are market requirements, fuel availability, and air quality regulations. The various calcining systems and their relative advantages and disadvantages are described in the next section.

Types of Lime Kilns

Vertical Kilns

Vertical kilns (also known as vertical shaft kilns or shaft kilns) traditionally have burned only larger stone, 75 to 300 mm, with a size range of approximately 1:2. Newer designs, however, can manage stone sizes as small as 20 mm and a wider size range up to 1:4. Relative lower fuel consumption is a major advantage of shaft kilns, which normally require less than 5.2 kJ/t of lime produced. This has been improved with newer designs, which operate as low as 3.3 to 3.9 kJ/t of lime produced. The use of oil, natural gas, or coke for fuel is one disadvantage of traditional vertical kilns in the energy environment of today; however, progress in burner technology has made it possible to utilize pulverized coal in modern shaft kilns.

Vertical kilns may be built of stone masonry, reinforced concrete, or boiler plate construction. The most widely used kiln has a refractory-lined steel shell and is usually circular in cross section. These may be 2.7 to 7.3 m in diameter and 15 to 48.5 m high. Capacities vary from as low as 8.2 tpd to in excess of 576 tpd, with the newer generation of kilns producing the higher range of tonnage.

Among the newer vertical kilns are the center burner, gas-fired (Azbe, Union Carbide), oil-fired annular (Catagas, Beckenback), and the Beckenback double-incline (Cascade). Also, several multiple-shaft parallel-flow regenerative kilns are now operated in the United States.

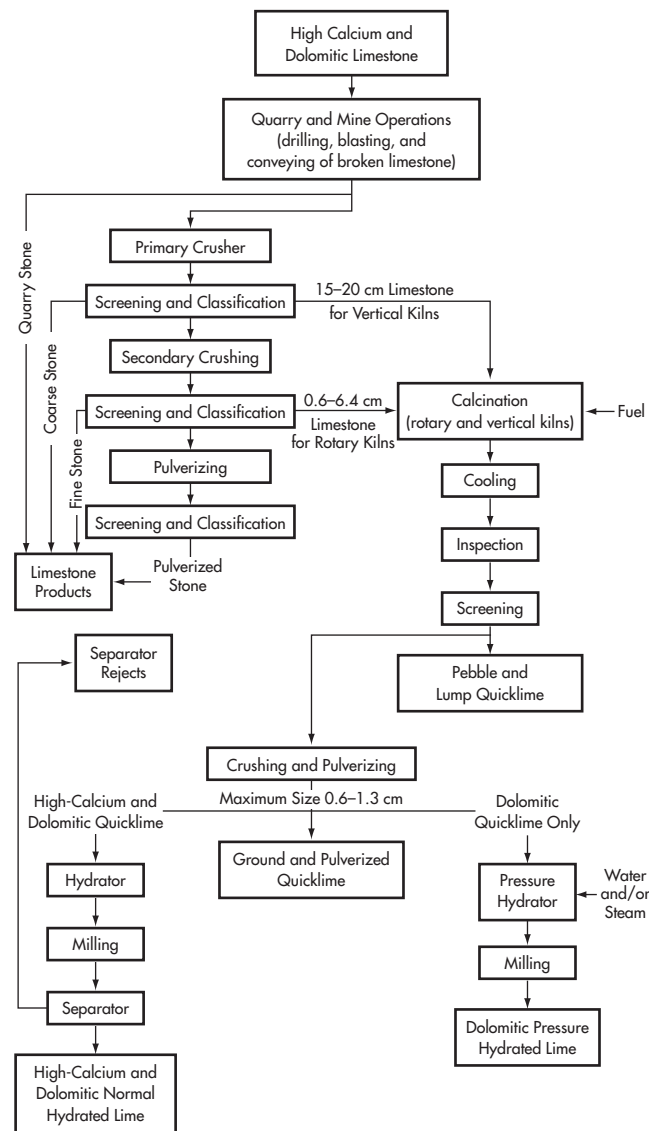

Older-style vertical shaft kilns are used by sugar companies processing sugar beets. These kilns tend to be lower in volume, less than 227 tpd, and are captive to their respective sugar plants.

Multiple Shaft Kilns

Although multiple shaft kilns (MSKs) were developed to burn small stone with sizes of 20 mm to 120 mm, the newer technologies allow burning with sizes smaller than 20 mm. They utilize the parallel-flow calcining principle in double and triple shaft units. Shafts are interconnected in the burning zone, and, while one shaft is being fired, the other is preheated (Figure 3). Fuel and combustion air are supplied to the burning shaft from above and ignited at the upper end of the burning zone; the lime is then calcined in uniflow. Next, exhaust gases pass into the second shaft, preheating the stone in counterflow. After a 10- to 15-min interval, the shaft firing is reversed, and cooling air is blown into both shafts simultaneously. Because of this novel heat regenerative system, fuel consumption in MSKs is 3.5 to 4.0 kJ/t of lime produced. MSKs vary in capacity from 81.6 tpd up to 907 tpd. Although MSKs normally are fired with natural gas or oil, recent advances in burner technology have made it possible to fire the kiln with pulverized coal. Kilns of this type have had a favorable response from the industry on a worldwide basis, and several are producing lime in the United States.

Annular Shaft Kilns

The burning process in annular shaft kilns is based on counterflow for preheating and calcining, and uniflow for residual calcination. Partitions provided by an inner cylinder and by staggered bridges in the burning zone permit even distribution of heat and uniform downward flow of material through the kiln. Stone as small as 25 × 75 mm

Source: Boynton 1980.

Figure 2. Simplified flow sheet for lime and limestone products

can be calcined to produce a soft burned lime (i.e., higher reactivity lime versus hard-burned lime) using either oil or natural gas for fuel. Capacities vary from 81.6 to 245 tpd with fuel consumption under 6.2 kJ/t.

Rotary Kiln

Unlike vertical kilns, which operate fully charged, the rotary kiln has about 90% of its volume filled with flame and hot gases. The kiln slowly rotates, exposing new surfaces of stone to the hot gases, but there is little flow of gases through the solids. Hence, radiation interchange among gas, solids, and the refractory wall is an important part of the overall heat-transfer mechanism. Rotary kilns are less efficient than shaft kilns because a relatively small area of the solids is exposed in a rotary kiln; they recover less heat from the exit gases of the kiln; and the radiant heat loss from the shell is much higher. Although the rotary kiln has the advantage of burning stone from 6.5 to 57 mm, the size ratio generally is 1:3 in order to

Source: Beach et al. 2000.

Figure 3. Multiple-shaft parallel-flow regenerative kiln

minimize segregation and to promote thorough calcination. While this sizing minimizes the amount of residual limestone core in the individual lime fractions, at the same time it allows a thorough soft burn of all the limestone feed. In addition, when using rotary kilns, it generally is not necessary to crush the final product, because it is in the form of an acceptable size of pebble lime.

Rotary kilns vary greatly in size, ranging from 2×25 m to 5.5×190 m, with capacities of 40.8 to 1,361 tpd. Because of the relatively high length-to-diameter ratio, these kilns have become known as long kilns. In North America, long kilns are typically 2.5 to 4.0 m \times 45 to 105 m long, producing 163.3 to 372 tpd of lime. The largest rotary kilns are 907 to 1,361 tpd capacity. Although rotary kilns can burn a wide range of fuels, a major drawback is their lack of fuel efficiency. Many of the earlier rotary kilns required in excess of 12.6 kJ/t of lime produced. This high fuel demand has been reduced to 7.4 kJ/t through the implementation of internal heat exchangers and dams, recuperative-type coolers, more sophisticated and complex instrumentation, and improved refractories.

Rotary Preheater Kilns

The most important improvement concerning the efficiency in rotary kilns is the move away from the long kiln to a medium-length kiln with an external preheater (Figure 4). The vertical, cylindrical, or shaft-type preheater kiln is available through Kennedy Van Saun (KVS; in 1989 KVS became part of Svedala Industries of Sweden and today it is part of Metso Minerals, Inc., of Finland), Fuller Company, and Allis-Chalmers. The preheater is a refractory-lined chamber located below the raw feed bin and in front of the kiln. Exhaust gases from the kiln are drawn countercurrent through the stone, preheating it to 540° to 900°C . Retention time within the preheater is 1.0 to 1.5 hr, depending on the design of the system, burning characteristics of the stone, and other factors previously listed. Even before the stone is discharged into the kiln, approximately 30% calcination is achieved during the preheating stage. Directly following preheating, the partially calcined stone is sent to the kiln at a predetermined rate by means of hydraulically actuated plungers. This type of preheater has been adapted to the new large-volume kilns, which typically may be 5.2 m in diameter by 62.5 m long, with a capacity of 816.5 to 907 tpd.

Allis-Chalmers also developed another type of preheater kiln, which is known as a grate kiln. This is a single-pass, downdraft, enclosed traveling grate on which finer-sized stone, placed on top of coarser-sized stone, is calcined while the coarser stone is preheated. In the rotary kiln, the coarser stone is calcined, and the finer stone is protected from overburning, having sunk into the kiln load through a sifting action. Grate-kiln systems of 245 to 490 tpd capacity are in operation in North America.

Heat exchangers and coolers that recuperate waste heat also are utilized to improve fuel efficiency. Heat exchangers, principally trefoil or quadrant sections, are mounted at the feed end. Their purpose is to turn the stone over more effectively and to increase the turbulence of the hot gases. Dams and lifters may be used to turn the stone over, create gas turbulence, or retard the passage of the stone. Coolers, on the other hand, located at the discharge end of the kiln, serve to return hot gases to the kiln as secondary air. Three types of coolers generally are used with the rotary kilns: the shaft or contact, the planetary, and the rotary. The most prevalent type is the Niem's contact (counterflow), which is refractory lined and mounted below the kiln hood. Cooling air is provided by a fan of sufficient size to reduce the lime temperature to 65°C or less. The planetary cooler consists of eight or more tubes, approximately 4.2×6.2 m in size, mounted at the discharge end of the kiln. Lime is moved in each tube by conveyor flights counterflow to the cooling air. The rotary cooler is generally not as effective as the other two cooler types and has the additional disadvantage of attrition loss during rotation.

The net effect using both shaft and grate preheaters, and improved heat exchange recovery within the kilns, is to reduce fuel ratios in rotary kilns from 4.7 to 6.3 kJ/t of lime produced. In addition, advances in instrumentation and monitoring have reduced worker requirements and increased product quality and uniformity. Together with these advances, the large-capacity rotary kiln with preheater has become the most commonly selected system today for new or expanded lime production facilities.

Calcimatic Kilns

The rotary hot calciner, or calcimatic kiln, consists of a preheater, circular hearth, and cooler, which are all refractory lined (Figure 5). Like the rotary kiln, this kiln can burn small stone, which is typically sized at a 1:3 ratio. The stone is carried on the hearth in a thin layer, and one revolution of the hearth constitutes the calcining cycle. Numerous burners inside and outside the hearth are used for firing,

Figure 4. Preheater rotary kiln system used in lime production

utilizing gas, fuel oil, coke oven gas, and, more recently, pulverized coal. Fuel requirements approximate 7.7 kJ/t and can be adjusted to accommodate a wide range of calcination. A significant advantage of the calcimatic kiln is that mechanical attrition loss is negligible. Stone is set virtually motionless on the hearth, permitting the utilization of soft limestones that otherwise would be subject to high mechanical degradation (decrepitation) during calcination. At present, only a few companies operate calcimatic kilns in North America, although there are several 81.7- to 245-tpd capacity kilns in use in Europe.

Fluo-Solids Kilns

For limestone that is friable or decrepitates during calcination, the Dorr–Oliver Fluo-Solids kiln, which is a fluidized-bed system, has been used to produce a highly reactive lime (Figure 6). In this fluid-bed process, the material is maintained in suspension in a rising current of hot gases until calcined. Kiln feed is normally 60 to 65 mesh in size. The system can be fired with natural gas or oil and incorporates a FluoDry unit (preheater) and a FluoSolids reactor (calciner) that resembles a rotary kiln. Fuel consumption is approximately 7.8 kJ/t of lime produced. Fluid-bed calciners are available in size ranges of 40.8 to 204 tpd; however, the only kilns of this design in North America are operated by Specialty Minerals Inc. at its North Adams, Massachusetts, plant.

Flash Calciners

The flash calciner is one of the more recent developments in calcination, but it is not really a kiln. Developed by Fuller Company, this system is designed to calcine the undersized material, or fines, that remain after the primary kiln feed is sized. There are three elements to this system: a preheater, a flash calciner, and a cooler. Preheating is achieved in a series of cyclones where the heat from rising hot gases is absorbed in the counterflowing material, which is fed from

Source: Beach et al. 2000.

Figure 5. Calcimatic kiln with cross-sectional view of one firing zone

the top, and attains a temperature up to 980°C. As the preheated feed drops into the furnace or calciner, a forced air vortex flow pattern pulls the particles into the center of the furnace and then up the sides before discharge. In the furnace, the temperature is 1,200°C, but retention time is only a few seconds. A suspension-type cooler recovers heat from the calcined product before it is conveyed to the product bin. The system is designed in two modes depending on the size of the feed. Where limestone fines are to be calcined, 60% to

Source: Beach et al. 2000.

Figure 6. Fluidized bed kiln

80% of calcination occurs in the furnace. The final calcination takes place in a fluid bed located between the furnace and the cooler. In systems where material of -28 mesh is fed to the calciner, no fluid-bed reactor is necessary. This system can utilize natural gas, oil, or coal, and will normally require 6.2 to 8.5 kJ/t of product.

Milling and Hydrating

After cooling, quicklime is carefully inspected to avoid unburned limestone core, or pieces of uncalcined rock. This is particularly necessary for shaft kilns that burn large stone. The quicklime is then crushed and sized for shipment. Generally, fines are converted to hydrated lime.

Hydrated lime is shipped in 23-kg bags or in bulk and typically is available in two forms: standard or normal grade with 75% to 95% passing a No. 200 sieve (75 μm); and fine grade where 99.5% passes a No. 325 sieve (45 μm). These in turn are manufactured in two types: Type N (normal) and Type S (special, see ASTM C 207-04), each including high calcium or dolomitic hydrates, respectively.

Type S limes are hydrated to a high degree by processes involving steam pressure. They contain less than 8% nonhydrated oxides and develop high and quick (15 min) plasticity and high water retention. Demand for Type S lime grew rapidly after World War II, and currently it is the chief lime for structural uses. Lime manufacturers now add air-entrained catalysts into the lime to increase plasticity and durability (called Type SA and Type NA lime).

A variety of mechanical hydrators are designed for the production of Type N lime, including batch hydrators such as the Clyde and continuous hydrators such as the Kritzer, Schaffer, Knibbs, Harding, and KVS (see National Lime Association 1995 for an excellent discussion on types of slakers). In the hydration process, water is added slowly to quicklime (usually in crushed or ground form), and the lime is agitated to produce intimate contact of lime and water. Accurate proportions are ensured by using flowmeters for water and weighing feeders for lime. Water exceeding the theoretical requirement for hydration is necessary, because some water is lost as steam from the heat of hydration. Following hydration, the product typically is fed to a pulverizer or tube mill equipped with an air separator. The air separator rejects core and most of the siliceous and alumina impurities. Various grades of hydrated fines are made by adjusting the separator.

Type S hydrate dusts are manufactured by various processes, but the principal one is the Corson explosion method of continuous pressure hydration. In this process, ground dolomitic quicklime and water are fed automatically into a high-speed slurry mixer in constant and exact proportions. Hydration then takes place in an insulated autoclave that operates at about 5.3 kg/cm² at 150°C. After about 30 min of retention time, the product is discharged continuously (or exploded) through a small pipe at 3,050 m/sec into a special cyclone collector at atmospheric pressure. There the hydrate and water are separated by the spray-drying principle. To increase plasticity, the product is ground in a tube mill. Several U.S. plants use the Corson process, marketing their products under the registered trade name Miracle Lime.

MARKETING

Uses

Lime is one of the top five chemicals produced and used in the United States. Its level of consumption reflects both economic conditions as well as changing consumption patterns. For example, in 1990 the major end uses were the following:

- Chemical and industrial, 66% (includes 29% in steelmaking, 7% in paper and pulp, about 4% in sugar refining, and 1.5% in precipitated calcium carbonate)
- Environmental, 24% (includes 9.6% flue gas desulfurization)
- Construction, 8%
- Refractory dolomite, 2%

Captive lime included in the se figures was used mainly in sugar refining and the production of steel. These figures are based on data from Miller (1991).

The major end uses in 2003 were for the following (Miller 2003):

- Metallurgical, 35% (includes 29% in steelmaking)
- Environmental, 28% (includes approximately 18% in flue gas desulfurization)
- Chemical and industrial, 23% (includes 4% in paper and pulp and nearly 7% in precipitated calcium carbonate)
- Construction, 13%
- Refractory dolomite, 1%

Captive lime accounted for less than 8% of consumption and was used mainly in the production of steel in basic oxygen furnaces, sugar refining, magnesia production, and refractories.

Steelmaking

Over the past 40 years, the steelmaking industry has been the largest consumer of lime. Although this situation continues today, the industry has seen a decline in sales. In the United States, from 1980 to 1990, lime consumption in the steel market dropped from 6 Mt (38.1%) to 4.6 Mt (29.4%) of lime production. Since then, up until the year 2003, lime consumption for steelmaking has hovered at about 29% to 31% of annual lime production. The U.S. importation of both steel and automobiles has caused decreasing lime requirements for steelmaking. Also, the use of more polymer composites in car and truck design and manufacturing, along with greater steel production from mini-mills, reduced the demand for lime in steelmaking.

Nevertheless, the basic oxygen furnace (BOF) is still the dominant steelmaking process and continues to utilize approximately 80% of the lime sold for steel production. The lime required for a typical BOF process is 60 to 65 kg/t of steel produced, versus an average of 30 kg/t of steel produced in an electric furnace or mini-mill. Both these applications use lime as a scavenger or flux to

remove impurities such as phosphorus, silica, alumina, and sulfur. While quicklime is the product of choice for a BOF furnace, 10% to 30% of dolomitic quicklime is used with high-calcium lime to extend refractory life. Dead-burned dolomite, or refractory lime, is used in open hearth steel furnaces for the same reason.

Lime used in steel production is normally highly reactive at 90% to 93% available lime with less than 0.06% sulfur. Either pelletized lime or pebble lime (1.25 to 5 cm in diameter) normally is required. A recent development in steelmaking (known as the Q-BOP, or Quelle Basic Oxygen Process) is the use of ground or pulverized lime that initially was used in European mills. The steel industry also uses lime in wire drawing steel plants for the following:

- Removing SO₂ in flue gases in the sinter plant
- Neutralization of sulfuric pickle liquors
- Effluent water softening and treatment
- Coating molds for pig casting

Experiments making a self-fluxing ferrous sinter with hydrated lime have assessed the feasibility of using hydrated lime instead of pulverized limestone.

Nonferrous Metallurgy

In 2003, nonferrous metallurgy utilized approximately 1.07 Mt of lime per year, or about 5.5% of total U.S. lime consumption. Recovery of nonferrous metals from their ores normally involves processing them through some form of flotation method. Lime is used to control pH, neutralize sulfuric acid waste liquors, or curtail the loss of cyanide in processes employing cyanide. Lime is used to neutralize the acidic effects of pyrite and other iron sulfides associated with base metal ores. It also acts as a flux in the sintering of low-carbon chrome and in the recovery of nickel by precipitation.

Gold. Lime controls the pH of sodium cyanide solutions used to leach gold and silver from their ores. When large particles of ore are involved, the process is called *dump leaching*; when particles of ore are small, it is called *heap leaching*; and when the ore is leached in agitated tanks, it is called *carbon-in-pulp cyanidation*. These leaching operations require crushing the ore, mixing it with lime for pH control and agglomeration, and stacking the ore in large heaps or pads for treatment with cyanide solution. Lime is used to maintain the cyanide solution pH between 10 and 11, which maximizes the recovery of the precious metals and prevents the formation of hydrogen cyanide. Lime also is employed to extract uranium from gold slimes.

Lime is used to treat tailings from precious metals mining, which may contain elevated levels of cyanides. Lime also can recover cyanides in treatment processes such as alkaline chlorination, Caro's acid (H₂SO₅), Cyanisorb, and sulfur dioxide/air (Miller 2003).

Copper. Most domestic copper mining companies use lime as the principal reagent in beneficiating copper ores during flotation. Lime neutralizes the acidic effects of pyrites and maintains the proper pH. Pebble lime is used in smelters as a flux to react with silica, alumina, and other impurities forming a molten slag. Employed to scrub SO₂ from stack gases of copper smelters, lime is used similarly as a flux in the smelting of lead, zinc, and antimony.

Alumina. The manufacture of alumina by the Bayer process frequently requires large quantities of lime to causticize sodium carbonate solutions that are used to regenerate sodium hydroxide for recycling. Nearly all plants use some lime for secondary desilication in refining alumina. The U.S. Bureau of Mines (USBM) required lime for experimental processes in which alumina was made from clay or kaolin rather than from bauxite.

Magnesia. Most methods for the manufacture of magnesia, such as the Dow seawater and natural brine processes, ferrosilicon processes, and seawater magnesite processes, require lime. Although dolomitic lime generally is preferred because of its magnesium content, high-calcium lime also is used with success. Dolomitic lime, however, cannot be used in the manufacture of magnesium metal, because this process requires a very high-purity, high-calcium lime.

Pulp and Paper

In the basic kraft pulping process used in the paper industry, wood chips and a liquor of sodium hydroxide and sodium sulfide are heated in a digester. The cooked wood chips, or pulp, are discharged under pressure, along with the spent liquor; the pulp is then screened, washed, and sent directly to make paper or for bleaching. Sometimes lime is used to produce calcium hypochlorite bleach for bleaching paper pulp. The spent liquor enters a recovery furnace where dissolved organics are burned to recover waste heat, sodium sulfide, and sodium carbonate. The sodium sulfide and sodium carbonate are recovered and diluted with water before treatment with slaked lime recausticizes the sodium carbonate into sodium hydroxide (caustic soda) for reuse. Pulp mills recover 90% to 96% of lime employed in the process by reclaiming dewatered calcium carbonate sludge, which occurs as a by-product of caustic soda production. It is still necessary, however, to purchase significant quantities of lime to make up the difference. The paper industry also uses lime as a coagulant aid in the clarification of plant process water.

The global competition from low-cost Asian imports has forced the U.S. paper industry to reduce capacity in recent years. In 2003, lime consumption in the U.S. pulp and paper market decreased by more than 11% (Miller 2003).

Lime is used to make precipitated calcium carbonate (PCC) that serves as a specialty filler and coating for premium-quality papers. In the United States, the most commonly used method to produce PCC is the carbonation process, where CO₂ bubbles through milk-of-lime to form a precipitate of calcium carbonate and water. Reaction conditions determine the size (<5 µm) and shape (uniform spheres of multiple scalenohedral calcite, rhombohedral calcite, or acicular aragonite, or crystal twins) of the resulting PCC crystals. A shift in U.S. paper manufacturing from clay to alkaline sizing in the 1980s increased the use of PCC, which enhances the qualities of paper: whiteness, brightness, opacity, gloss, pH neutrality, and bulk.

Precipitated Calcium Carbonate

Specialty Minerals, Inc. (formerly Pfizer Specialty Minerals, Inc.) pioneered the concept of onsite PCC production in which PCC facilities are adjacent to the paper mill. It was this innovation that expedited the conversion from acid-based to alkaline-based paper-making technology. Some lime companies operate onsite PCC plants in order to make a value-added product available to their customers. Carbon dioxide captured from kiln stack gases is used in the adjacent PCC plant.

PCC also is used in the manufacture of polyvinyl chloride (PVC) plastics and in pharmaceuticals, such as antacid tablets and calcium and other mineral supplements. It is added to sealants and adhesives for rheological enhancement and is used as an industrial filler in paint and inks, rubber products, and thermoplastics. Special applications include use in problem powders as an anticaking agent and for flow improvement by reducing interparticle attractions and by absorbing moisture. Because of its relatively high surface area, PCC can also be used as an inert carrier for liquid catalysts.

Chemicals Manufacture

Lime is used in the manufacture of many chemicals.

Alkalies. In the manufacturing of soda ash and bicarbonate of soda, the Solvay process employs lime to recover ammonia for reuse, requiring 635 kg of quicklime per ton of soda ash produced. In the process, lime reacts with chloride ions to form calcium chloride, which is recovered and sold commercially. The process also yields by-product PCC that is recycled and reused. In addition, lime causticizes sodium carbonate solutions to produce sodium hydroxide (caustic soda). Lime usage for this application, however, has dropped tenfold over the last 10 years as the Solvay process has lost most of its market share to natural soda ash (trona) and electrolytic caustic soda.

Inorganic Chemicals. Inorganic chemicals made from lime include mono-, di-, and tricalcium phosphates, chrome chemicals, purifying salt brines used to produce U.S. Pharmacopeia (USP) food-grade salt, pesticides such as lime-sulfur sprays and powders, and calcium arsenate. Hydrated lime also can be found in proprietary water paints that are used in masonry applications, white portland cement, and some paint pigments. Lime has minor uses in varnish manufacture, celiac pain ts, and certain performance pigments.

Organic Chemicals. Lime is required in the manufacture of ethylene and propylene glycols in the chlorohydrin process in calcium-based organic salts, such as calcium stearate, acetate, lactate, and lignosulfonate. It also is used in the manufacture and refinement of citric acid and glucose. In the petroleum industry, lime has a limited role in neutralizing organic sulfur compounds and SO₂ emissions control in oil refineries. It also is used in the manufacture of certain lubricating greases and drilling muds.

Environmental

Lime use for environmental purposes ranges from smelting stack scrubbing to water treatment. Its primary features in this regard are its diacid nature and its reactivity.

Water and Wastewater Treatment. More than 1.38 Mt of lime was used in 2003 in the United States for the treatment of municipal potable water and industrial wastewater. Lime or lime in combination with soda ash is used to soften water in systems where ion-exchange processes are not employed. Its purpose is to eliminate temporary calcium and magnesium bicarbonates, or hardness, from the water. By raising the pH to 11.5 or higher and by temporarily raising water temperature, lime serves as a secondary sterilization agent to chlorine. With retention times of 3 to 10 hr at this high pH, 99% of waterborne bacteria and most viruses are killed. Afterward, CO₂ is introduced into the lime-treated water, returning pH to an acceptable level and reacting with most of the lime to precipitate and form calcium carbonate sludge.

When surface waters (rivers, lakes, and reservoirs) are used for potable water, lime together with the coagulants alum and iron salt helps to eliminate turbidity; that is, suspended and/or colloidal matter is removed. Here, lime controls pH, neutralizing the acidic effect of the coagulants and achieving optimum efficiency in coagulation.

As an added benefit, after lime returns the pH to lower levels, say between 5 and 8, aluminum, iron, manganese, and other heavy metals, as well as organic compounds (such as tannins), are removed from solution. The control of pH also minimizes corrosion of water pipes and equipment. The benefits of water softening in municipal water systems include the ability of soaps and detergents to lather; the reduction of scale formation in pipes and valves; and improvement in the taste of drinking water.

In the treatment of sewage effluents and wastewater, lime serves the following functions:

- Acid neutralization
- pH control during treatment or before discharge
- Precipitation of metals including heavy metals
- Precipitation of sulfates and fluorides (at pH >10)
- Reduction of nutrients (e.g., phosphates and nitrogen at pH >10), particularly to prevent eutrophication in surface waters
- As an efficient and cost-effective disinfectant

Lime modifies wastewater sludge in a positive manner (by improving settling and filtration in a dewatering coagulation) and through the flocculation of solids; by reducing its moisture content through the hydration of quicklime; and by adding strength for landfill disposal.

Over the last decade or so, federal and state environmental requirements for sewage treatment became more stringent. As a result, chemical treatment processes have become more important and preferred over biological sewage treatment processes.

In addition to potable water and sewage treatment, lime also is used in a variety of methods directed at treating industrial wastewater. For example, lime can neutralize acid mine drainage and precipitate iron in coal-washing plants. Wastewater from sulfuric acid pickling plants and plating waste are neutralized with lime, as are chemical and pharmaceutical plant wastes.

Flue Gas Desulfurization. An entire chapter is devoted to FGD in this book. It is only mentioned briefly in this chapter.

In 1990, the Clean Air Act Amendments included new source performance standards that required a much higher level of sulfur removal from stack gases of coal-fired electric power-generating plants and caused the market for lime used in FGD to increase accordingly. In 1990, 1.673 Mt of lime (9.6% of total sold and used lime) was consumed for FGD in the United States; in 2003, the figure rose to 3.440 Mt of lime (17.9% of total sold and used lime)—an increase of more than 100% or just more than double the amount used prior to the Clean Air Act Amendments.

Coal contains up to 4% sulfur by weight in the form of iron sulfide (iron pyrite; FeS₂), organic sulfur compounds, and inorganic sulfates. When coal is burned, sulfur is oxidized to SO₂ and minor amounts of sulfur trioxide (SO₃). Sulfur dioxide can combine with water in the atmosphere to form H₂SO₄. The application of lime in flue gas scrubber systems removes SO₂ from smokestack gases, which is accomplished by several methods:

- Wet scrubbing with milk-of-lime
- Semidry scrubbing with milk-of-lime using a spray drier or circulating fluidized-bed technology
- High-temperature (>850°C) dry injection of hydrated lime
- Low-temperature (<300°C) injection of hydrated lime
- Low-temperature (<300°C) absorption by hydrated lime in fixed bed

In addition, these methods may be used to remove other acid gases such as hydrogen chloride and hydrogen fluoride, as well as nitrogen oxides.

The United States, Germany, and Japan are the leaders in FGD technology and research, which is in its initial development phase. More recent industrial research has been directed to the task of FGD; for example, the emissions of dioxins, furans, and volatilized heavy metals.

Major problems associated with the processes of FGD include the cost and efficiency of the technologies, as well as the

issue of how to dispose of the reaction products (e.g., landfill versus by-product utilization such as synthetic gypsum for wallboard manufacture).

Construction

Prior to the 20th century, lime was used in construction for such diverse applications as whitewash and masonry mortars.

Soil Treatments. Lime has three major applications for soil treatments: drying wet soils; modifying clay-rich soils; and soil stabilization. Basically, modifying wet soils at construction sites involves the drying of mud. Dry soils provide stable platforms for heavy equipment, an extended working season in wet climates, and stability of soil embankments and engineered fill. Lime is spread on the soil, mixed into the upper 30 cm of soil, and, finally, compacted. When quicklime hydrates on application, lime offers a relatively immediate reaction time (4 to 24 hr). During the hydration process, the quicklime absorbs water and generates heat, providing additional evaporation.

In the modification of clay-rich soils, the desired reaction typically occurs within a time span measured in hours. Specifically, soil modification is an ion exchange between the calcium cation supplied by lime and the sodium and potassium cations contained in the clay. After flocculation and agglomeration of the soil has occurred, plasticity and swelling are reduced, and friability is increased, making the soil easier to work and compact and reducing the ability of soils to retain moisture.

In soil stabilization, lime is mixed with soils to react with siliceous and aluminous soil components, generating long-term increases in soil strength resulting from a pozzolanic effect. Early in the reaction, the formation of hydrous colloids and gels slowly crystallize into calcium silicates and calcium aluminates. The reaction can continue over long periods of time, providing the pH remains high and as long as lime is present. The amount of lime applied to soils for stabilization ranges from 3% to 5% of dry soil weight. When hydrated lime is used, it typically is applied in slurry form. Slaked lime slurries made with pebble quicklime may also be used; however, when using quicklime, it is critical that it be soft-burned, high-calcium lime with less than 10% residue on slaking. Low-residue lime produces higher cure strengths in soils than does lime with large residues. All federal agencies and most state highway departments have recognized the advantages of soil stabilization with lime, and thousands of kilometers of interstate highways in the United States have benefited from this system.

The application of lime for soil stabilization provides soils that are homogeneous, impermeable, and stable. Soil stabilization with lime also reduces soil plasticity and the amount of density changes (shrinking and swelling). In addition, lime applied to soils will increase soil compressibility, tensile strength, and flexural strength. Sites that are good candidates for soil stabilization using lime include roads, runways, parking lots, temporary haul roads, landfills, and building foundations and/or footings.

Lime Fly Ash (Lime Kiln Dust). Lime kiln dust (LKD) mixes were first introduced by the Corson Company in a proprietary process called Poz-O-Pac. Since then, LKD pozzolanic mixes have achieved increased acceptance with their success. In this process, lime is mixed with kiln dust, aggregate, and a small amount of water, usually in a pug mill, at a central mix plant. Controlling moisture is critical for the proper pozzolanic reaction and the resulting level of strength in the subgrade. The product may then be laid down either with standard paving equipment or by utilizing a compaction method.

Mortar. For thousands of years, lime was used in mortar and continues to be used even today. Before the advent of portland cement in the late 19th century, mortars were composed of lime and

sand. Today lime-cement mortars are used with varying proportions, ranging from one-quarter to three parts of lime by volume to one part of cement. Lime is still the most dependable plasticizer for mortar, making it workable and more trowel-able, or cohesive. In the cement-lime mixes, the cement provides the rapid set. These type of masonry mixes, however, encounter severe competition from masonry portland cements.

A similar application for lime is found in plasters. At one time it was used in base plaster coats, but these generally have been replaced with gypsum wallboard. In interior plastering today, lime is still used in the finish, or white coat, and is usually mixed with gypsum. In California and Florida, or other places with warm climates, lime also is used in exterior plaster or stucco as a mixture with portland cement and sand in varying proportions.

Asphalt. The addition of 1% to 1.5% of hydrated lime to asphalt hot mixes has a number of advantages in road construction. Lime acts as an anti-stripping agent, preventing the aggregate from raveling from the bituminous cement binder in the presence of water. In reducing the asphalt's sensitivity to water, cracking and potholes are reduced. In remote areas, lime permits the use of marginal, unwashed aggregates, and, where necessary, it serves as filler. Based on the immersion compression test with some asphalts and aggregates, lime markedly increases the wet/dry strength ratio and reduces volume change (swelling and shrinking). Lime-charged asphalt mixes prevent oxidation of the asphalt binder and the effects of aging, such as brittleness and cracking. In improving the stiffness of the asphalt binder, the tendency toward rutting is reduced.

Hot lime slurry is now being added to the asphalt emulsion in cold in-place recycling of distressed asphalt pavements. This mixture is placed and compacted using conventional paving techniques, providing a smooth base for the new asphalt surface. Lime use in cold in-place recycling adds greater early strength and resistance to moisture damage.

The American Society for Testing and Materials' (ASTM's) committee on lime, Committee C07, has adopted specifications for the use of hydrated lime in asphalt and asphaltic concrete mixtures. Nevertheless, professional biases within the construction industry continue to foster some resistance to the use of lime in asphalt, even though its advantages are well known.

Agriculture

Since Roman times, lime was used in farming. Today the role of lime in agriculture is expanding.

Sugar Refining. Although sugar refining normally is included with most chemical or industrial lime use statistics, in reality it is an agricultural application. Lime is essential for making sugar in both sugar beet and cane sugar refining processes. Sugar beet refining requires a significantly higher volume of lime than does cane sugar. On average, beet sugar requires 200 kg of quicklime per ton of sugar, whereas cane sugar requires only 1.9 to 4.9 kg/t of lime. During sugar refining, milk-of-lime raises the pH of the product stream, precipitating colloidal impurities. These impurities, normally phosphatic and organic acid compounds, are removed from the stream by filtration. Most sugar beet plants have captive lime plants onsite so that CO₂ kiln stack gas resulting from limestone calcination can be captured and used during carbonation in the sugar refining process.

Agricultural Lime. Although most agricultural liming today is achieved with pulverized limestone, some farming still uses ground quicklime or hydrated lime. This is particularly true in truck farming where lime is able to neutralize soil acidity more rapidly and maintain a pH level that allows for three crops to be grown per year. The added cost for lime is easy to justify in higher value

Table 6. U.S. lime industry statistics

Statistic	Year				
	1980	1985	1990	1995	2000
Quicklime sold or used, <i>ktpy</i>	17,200	14,200	15,800	18,500	20,100
Number of lime plants	153	119	113	113	107
Average kilotons per plant	112.4	119.3	139.8	163.7	187.8
Average selling price, \$/t	49.00	57.00	57.10	59.50	60.60
Average selling price, constant 1998 \$/t	97.00	86.40	71.20	63.60	57.37

crops. In some sandy soil areas, only dolomitic lime is used, because of persistent magnesium deficiencies.

Feedlot Applications. Corporate farming and husbandry practices over the past several decades have led to the establishment of large facilities for raising farm animals in rural areas. Attention has been drawn to environmental issues, including the facilities' potential impacts on public water supplies, and the concerns of nearby residents. Federal and state agencies dealing with environmental quality now regulate the effects—mostly from animal waste products—that swine waste lagoons, cattle feedlots, and chicken farms, for example, may have on rural areas. Applying lime to wastewater effluent or feedlot soils increases their pH and temperature to high enough levels to destroy most harmful bacteria and viruses and reduces unpleasant odors associated with animal wastes. In addition, lime applied to areas affected by animal wastes fixes hazardous pollutants and helps to decrease harmful nitrogen (ammonia) levels. Quicklime hydrates when applied to animal waste sludge, resulting in water absorption and heat generation that provides additional evaporation. Lime also imparts strength to the sludge, making it easier for landfill disposal or composting.

Other. Lime is used as a CO₂ absorbent in controlled atmospheric storage for fresh fruit and certain vegetables to extend the freshness of the produce. This prevents CO₂ from building to abnormally high levels, which would accelerate the rotting of produce. Lime is also used to recover glue and gelatin from packing house by-products. In citrus fruit processing, lime is employed to treat the waste pulp, which, after grinding and drying, is sold as cattle feed.

Specifications and Testing

Because of the many types and uses of lime, plus their wide variety of physical and chemical characteristics, there are different specifications for lime products for most major consumers, even for individual companies or plants.

The National Lime Association, along with its member companies and the majority of lime consumers, subscribes to ASTM specifications on lime, promulgated by Committee C07. The specifications cover many uses and testing procedures:

- C25-99: Standard Test Methods for Chemical Analysis of Limestone, Quicklime, and Hydrated Lime
- C50-00: Standard Practice for Sampling, Sample Preparation, Packaging, and Marking of Lime and Limestone Products
- C51-05: Standard Terminology Relating to Lime and Limestone (as used by the industry)
- C110-05: Standard Test Methods for Physical Testing of Quicklime, Hydrated Lime, and Limestone
- C400-98: Standard Test Methods for Quicklime and Hydrated Lime for Neutralization of Waste Acid

- C593-95(2000): Standard Specification for Fly Ash and Other Pozzolans for Use with Lime
- C602-95a(2001): Standard Specification for Agricultural Liming Materials
- C706-02: Standard Specification for Limestone for Animal Feed Use
- C737-02: Standard Specification for Limestone for Dusting of Coal Mines
- C821-78(2000): Standard Specification for Lime for Use with Pozzolans
- C911-99: Standard Specification for Quicklime, Hydrated Lime, and Limestone for Chemical Uses

Although these are some primary tests and specifications for lime, it is not a complete or comprehensive list. For a complete listing, the reader is referred to ASTM in West Conshohocken, Pennsylvania (www.astm.org). For a quick reference on some European (CEN) and British (BS) specifications, see Oates 1998.

Another important lime specification promoted by the American Water Works Association (AWWA; <http://www.awwa.org>) is ANSI/AWWA B202-02 on quicklime and hydrated lime (AWWA 2002). This includes a bonus and penalty arrangement based on available lime content, slaking rate, and slaking residue. It also applies to sewage and industrial waste treatment plants.

ASTM procedures are used in testing lime intended for FGD; however, many specifications are based on U.S. Environmental Protection Agency (EPA) performance standards and apply to a specific utility. Consequently, individual utility customers may have specifications that exceed normal ASTM standards.

Product Pricing

Lime is considered a commodity mineral that has low to moderate unit value and high place value. Table 6 shows the trends in the U.S. lime industry over the last two decades (Krukowski 2004). As the industry took advantage of economies of scale, the number of plants producing lime decreased while increasing domestic production. As a result, the average annual output per plant increased from 112,400 to 187,800 t over the time period 1980 to 2000. In that same period, the actual average selling price rose from \$49.00 to \$60.60/t; however, the average selling price in constant 1998 dollars went from \$97.00 to \$57.37/t, primarily because of overcapacity.

During the period from 1910 to 1970, lime pricing was relatively constant and rarely exceeded \$15/t f.o.b. at the lime plant. Beginning in 1970, lime prices increased steadily because of fuel costs and government-mandated environmental controls. In 1974 the oil embargo initiated a substantial increase in energy costs, which were clearly reflected in the costs of production and, consequently, the cost of lime.

The average values per ton of various types of lime, rounded to three significant figures, are listed in Table 7. The data are reported by type of lime produced: high-calcium quicklime, high-calcium hydrate, dolomitic quicklime, dolomitic hydrate, and dead-burned dolomite. Emphasis is placed on the average value per metric ton of lime sold.

On average, prices rose by 4% in 2003, to \$64.80 for all types of lime sold per metric ton (\$58.80/st). This is the first significant evidence of price increases by major lime companies since 2001 (Miller 2003), which were instituted to compensate for increased costs of raw materials, environmental compliance, labor, and health care. The average value per ton of high-calcium quicklime, dolomitic quicklime, and dolomitic hydrate all increased, but the average value of high-calcium hydrate and dead-burned dolomite decreased. It is anticipated that a rise in fuel costs may lead to higher lime prices, especially when natural gas is burned; for

example, some lime plants stopped operating in 2001 when natural gas prices peaked.

Lime prices can be affected by whether contracts between buyers and sellers are long or short term. Long-term contracts tend to give the buyer an advantage if the seller is guaranteed demand for the product. Many factors can influence the price of a commodity, including the following:

- Economic climate (e.g., times of economic growth versus recession)
- Oversupply (e.g., when markets are saturated after new plants come on-line)
- Cost of production (e.g., when fuel costs increase)
- Competition from product substitutes
- Customer product specifications
- Distances to points of consumption

Substitutes

Limestone is a substitute for lime in many applications, such as agriculture, fluxing, and sulfur removal (e.g., in FGD). The advantage of limestone is its lower cost, but it is less reactive in terms of time and material (tonnage). In many chemical applications, NaOH may substitute for lime, especially in cases where pH control is concerned; however, hydrated lime is a diacid base, so smaller quantities are needed in some applications (e.g., acid neutralization).

Ground calcium carbonate (GCC) is a substitute for PCC in paper, PVC plastic products, and paint and other pigments.

Calcined gypsum is an alternative material in industrial plasters and mortars. Cement and LKD and fly ash are potential substitutes for some construction uses of lime; for example, in soil stabilization and hot-mix asphalt. Some organic compounds also may take the place of lime in soil treatment roles. Portland cement mortars have been a traditional alternative to lime in its use as masonry cement.

Magnesium hydroxide is a substitute for lime in pH control, and magnesium oxide is an alternative for dolomitic lime as a flux in steelmaking.

Recycling

Large quantities of lime (90% to 96%) are regenerated by pulp paper mills. Some municipal water treatment plants recycle lime from softening sludge. In the carbide industry, quicklime is regenerated from waste hydrated lime. In the production of caustic soda, lime is recycled for use in the chemical process.

Packaging and Transportation

Because of their large particle sizes, lump, crushed, pebble, or pelletized limes are rarely handled in bags. Therefore, most quicklime is shipped in bulk. Bags are made of multiwall paper with capacities of 22.7 kg (50 lb) or 36.4 kg (80 lb), and bulk bags up to 1.8 t (2 st). The finer sizes of quicklime (fine, granular, and pulverized) are shipped in bulk or in bags.

For many years, railroads were the primary carrier for bulk lime in the United States. The convenience of truck transport on U.S. interstate highways, however, reduced significantly the volume of bulk lime delivered by rail. Trucks used for shipping bulk lime are typically pneumatic tank carriers that can provide both an enclosed container and a safe handling system so the operator can avoid direct contact with the product. While truck and rail shipments are used to ship most bulk lime, an increasing amount is moved by barge on inland waterways.

In a number of locations, intermodal shipments of lime take advantage of barge and rail rates with low unit costs over long dis-

Table 7. Lime prices*

Type	2002		2003	
	\$/t	\$/st†	\$/t	\$/st†
Sold and used				
Quicklime	59.20	53.70	61.30	55.70
Hydrate	88.50	80.30	84.80	77.00
Dead-burned dolomite	86.70	78.70	90.80	82.30
Average all types	62.60	56.80	64.90	58.80
Sold				
High-calcium quicklime	58.50	53.10	61.00	55.40
Dolomite quicklime	59.80	54.20	62.10	56.30
Average quicklime	58.70	53.30	61.20	55.50
High-calcium hydrate	86.20	78.20	81.20	73.70
Dolomite hydrate	97.40	88.40	102.70	93.20
Average hydrate	88.60	80.40	84.90	77.00
Dead-burned dolomite	94.30	85.50	92.10	83.50
Average all types	62.30	56.50	64.80	58.80

† Conversions were made from unrounded metric ton values and may not be conversions of the rounded values.

tances. In these systems, bulk lime cargoes are unloaded at barge or rail terminals, stored in silos, then later transferred to pneumatic tank trucks for local delivery. For small customers located beyond the railroad or waterway, these systems allow them to take advantage of bulk transportation rates.

Although most lime is transported in bulk, hydrated lime frequently is packaged and shipped in bags or bulk bags. Paper bags weighing 22.7 kg (50.0 lb) normally contain a polyethylene liner to protect the lime from moisture and to ensure its satisfactory performance for the consumer. Bulk bags weighing 900 kg (1 st) lack the flexibility of sizing to customer requirements and may be larger or smaller in capacity. A variety of bulk containers include one-way and returnable bulk bags, cardboard "gaylords," and reusable metal containers.

Because of quicklime's affinity for water, and because it may slake by absorbing moisture from ambient humidity (air slaked), lime is considered a perishable product. It is recommended that quicklime not be stored in bags for more than 3 months, although it can be held for as much as 6 months. To protect quicklime from moisture, storage containers and transport media must be watertight. Bulletin 213 from the National Lime Association (1995) provides excellent discussions on the handling and storage of lime.

Economic Factors

Tariffs and Duties; Depletion Allowance

In the United States, the depletion allowance for limestone produced and used for lime from both domestic and foreign production is 14%. Under normal trade relations, there are no tariffs on quicklime, slaked lime, and hydraulic lime; however, there is a 3% ad valorem tariff on calcined dolomite. There is no U.S. government stockpile.

By-products

LKD is composed of very fine particulates trapped in air pollution control systems of rotary kilns used to manufacture lime. It is a mixture of dust from finely ground limestone kiln feed and fly ash from fuel (coal, fuel oil, natural gas) used for combustion in kilns.

If it contains a minimum amount of calcium oxide, LKD can be successfully employed in asphalt hot mix and for soil stabilization. Although it also has been used as an agricultural soil amendment, a complete chemical analysis is necessary before it is applied to agricultural soils to ensure the absence of any harmful elements. LKD may also be used for lightweight aggregates or as fill material.

Carbon dioxide generated from the dissociation of calcium carbonate in lime kilns is captured and used in the production of PCC. It is also captured from lime kilns in the sugar industry and used in the carbonation process in refining sugar from sugar beets.

REGULATORY AND ENVIRONMENTAL CONSIDERATIONS

Health and Safety

All mining and related activities in the United States are regulated by and come under the jurisdiction of the Mine Safety and Health Administration (MSHA). MSHA administers the provisions of the Federal Mine Safety and Health Act and enforces compliance with mandatory safety and health standards for the following purposes:

- Eliminating fatal accidents
- Reducing the frequency and severity of nonfatal accidents
- Minimizing health hazards
- Promoting improved safety and health conditions in the nation's mines

Persons working in mining operations, including the lime industry, must complete required health and safety MSHA training followed by annual refresher courses.

Short-term goals for MSHA include the reduction of respirable silica dust exposure in metal and nonmetal mines and the reduction of noise exposures. To maintain compliance, lime operators must monitor their plants and personnel. For these reasons, federal and state mine inspectors are required to visit mining operations on a regular basis and may arrive unannounced.

When water is applied to quicklime, its reaction may generate enough heat to cause paper, wood, or cloth to combust. Quicklime is classified as a Class E corrosive material that can destroy the skin and/or eat through metals. Additionally, it can cause severe eye and skin irritation on contact; cause severe tissue damage with prolonged contact; and may be harmful if inhaled. Proper personal protection equipment must be used in appropriate situations when close contact is anticipated.

Mining Regulation

Federal and state governments in the United States regulate the mining industry. This includes issuing mining permits that comply with statutes and regulations of the governing body. A permit is issued when the mine operator submits an acceptable application and posts adequate bond to cover reclamation costs. The mining permit application must include the requirements for legal and financial compliance, the safeguard of environmental resources, and an operations and reclamation plan. Bonds are not released until mine reclamation is complete.

Part of the permitting process typically allows for public notification and participation; the latter may include filing a protest against a pending permit or revision. Public meetings, usually held at a location close to the permit area, may be part of the process that includes participation of the public, the permit-issuing government agency, and the mine permit applicant. The first responsibility of the issuing agency is to ensure both statutory and regulatory compliance by the permit applicant; however, mine operators generally work with their neighbors and are willing to address their concerns. Nevertheless, it is the obligation and responsibility of prospective mine operators to know the laws and regulations under which they

must operate. See the section on Evaluation of Limestone Deposits in this chapter as well as the Limestone and Dolomite chapter in this book.

Air Quality Considerations

On August 25, 2003, the EPA issued a final rule to reduce toxic air pollutant emissions from new and existing lime plants. The rule was authorized by Section 112(c) of the Clean Air Act and set limits on hazardous air pollutants (HAPs) from commercial lime plants, captive lime plants at steel mills, captive lime plants at non-ferrous metal production facilities, and producers of dead-burned dolomite. The EPA has identified the lime industry as a source of HAP emissions that include hydrochloric acid and the metals antimony, arsenic, beryllium, cadmium, chromium, lead, manganese, mercury, nickel, and selenium.

The final rule set particulate matter (PM) emission limits for lime kilns, lime coolers, and mineral-processing operations with stacks. PM is not a HAP but is considered a permissible surrogate for HAP metals. The PM emission limit for kilns and lime coolers is 0.10 lb/st of stone feed at a new lime plant, 0.10 lb/st at existing lime plants, and 0.60 lb/st of stone feed at lime plants with wet scrubbers (EPA 2003). The final rule went into effect with its publication in the *Federal Register* on January 5, 2004. Although the compliance date for existing lime plants will be January 5, 2007, new plants will have to comply immediately (Miller 2003).

OUTLOOK AND FUTURE TRENDS

Because lime is a commodity chemical with a myriad of applications in many industries, the long-term forecast is excellent. The U.S. lime industry is currently at production capacity and lime prices are increasing, a trend that began in 2001. Future success will depend on the ability of the industry to develop new markets.

Johnson and Roden (2003) recognized that environmental applications will continue to be the major growth area for lime in the future. Since passage of the 1990 Clean Air Act Amendments, the focus over the last 10 to 15 years has been on FGD. The EPA's Maximum Achievable Control Technology (MACT) program will likely continue to identify and implement tighter regulation of air pollutant emissions, including sulfur dioxide. This will especially be true for coal-fired electrical power-generating plants, but a broader base of pollutant emitters will be targeted beyond the utility companies. As the technology of smokestack scrubbing advances over time, the demand for lime and its application in this field should increase. The use of lime for the mitigation of stack pollution may be supplanted by other substances (unknown at present), but it still may find application in other sectors of the process (e.g., sludge treatment and control). Alternatively, Johnson and Roden (2003) speculate that lime may replace existing environmental treatment solutions that use more expensive and/or less effective reagents (e.g., caustic and magnesium hydroxide).

Environmental applications are not restricted to air pollution applications such as FGD. The Clean Water Act and enforcement efforts by both federal and state water quality departments will put tighter restrictions on municipal and industrial sewage and wastewater treatment plants as point-source polluters, thus expanding lime markets for environmental application. Additionally, lime's neutralizing effect can be used to control pH in acid lakes and reservoirs, which will positively affect aquatic life and make these bodies of water safe for recreation.

In solid waste management, lime will have a larger role in treating sewage biosolids and animal wastes, along with industrial sludge and solid hazardous wastes. Although its use in sewage treatment is well known, lime also is applied to biomedical, or hospital,

waste. (See the Environmental and Agriculture subsections in this chapter.) In the treatment of solid hazardous waste, lime stabilizes most metals to prevent their leaching into groundwater. The EPA has identified lime as suitable for pretreatment of hazardous wastes prior to landfill disposal. Stabilization and precipitation often are required of metals contained therein, and the EPA has endorsed lime for the task.

The lime industry is marketing its product for construction uses more aggressively. Two primary areas of focus are in soil stabilization and modification and in asphalt hot mix for highway construction. If the Transportation Equity Act for the 21st Century (TEA-21) is extended by the U.S. Congress, federal highway funding will be available for construction of U.S. highway systems. This means that increased amounts of lime will be necessary for road base stabilization and for the use of lime in asphalt hot mix for asphalt concrete.

In *Industrial Minerals and Rocks*, 6th edition, Freas (1994) discussed the implementation of statistical process control (SPC) and integrated process control (IPC) on the production side of lime manufacture. Much of the upgrades achieved in the 1990s in the industry included these concepts. The lime industry continues to upgrade its production facilities through refinements in software packages, which should lead to increased energy efficiency, reduced personnel, and a more consistent quality product.

Tables 8 and 9 illustrate additional trends in the U.S. lime industry. In the past, the means of production was domestically owned and dominated by family-run companies, while now it is dominated by large, foreign-owned, international corporations. In 1900, many small lime plants produced low tonnages, but today, the industry produces lime from a few large plants producing large tonnages. In the past, the plants were located as close to the consumer as possible, but today, although still relatively close to consumers, plants are closer to the resource, mainly because of advances in transportation.

Although the United States lagged behind the rest of the industrialized world in these trends, in the last 20 years the U.S. lime industry has learned to take advantage of economies of scale (the bottom line) and has seen more international ownership.

The consolidation within the lime industry and expanded foreign ownership of U.S. lime producers will probably continue, but at a slower pace.

ACKNOWLEDGMENTS

The author wishes to express gratitude to the authors of the Lime chapters from earlier editions of *Industrial Minerals and Rocks*: Robert S. Boynton and Kenneth A. Gutschick, authors of the 5th edition, revised by Robert C. Freas and Jeffrey L. Thompson; and Robert C. Freas, author of the 6th edition. The present edition relied heavily on its predecessors. The author also wishes to express his appreciation to James Derby and staff at Carmeuse North America for reviewing the section on lime manufacture.

ADDITIONAL RESOURCES

Because lime is one of the oldest materials known to humans, and its end-use pattern is diverse, the literature on lime is so extensive that it is impossible to give a complete bibliography. Many earlier bibliographical references can be found in the Lime chapters in the 5th and 6th editions of *Industrial Minerals and Rocks*. The following list of sources presents some general references as well as specific citations in the text. For the latest and up-to-date information on the industry, the following trade periodicals are excellent resources: *Rock Products*; *Pit and Quarry*; *Global Cement and Lime*; *Gypsum Lime and Building Products*; *Zement-Kalk Gipps*; and various USGS publications.

Table 8. U.S. lime production in the 20th century

Year	Production, t	Number of Plants	Major Uses	Major Producing States
1900	1,800,000	>1,000	Construction and building trades	Ohio and Pennsylvania
2000	19,600,000	107	Steel, environmental, chemical	Kentucky and Missouri

Table 9. U.S. lime industry trends during the 20th century

	Early 20th Century	Late 20th Century
Ownership	Family-owned or U.S.-owned	Large corporations, owned internationally
Plants	Numerous and small	Few and large
Production	Low tonnage	High tonnage
Plant capacity	Small	Large
Location	Near user	Near resource
Price, 1998 \$	Increasing	Decreasing*

* Lime prices began to increase in 2001.

Today, the Internet serves as the primary reference tool for many. The National Lime Association (NLA) maintains a Web site that lists many references for lime and its uses. Many NLA publications can be downloaded from the Web site, and interested readers are encouraged to do so. The NLA lists several excellent Web sites belonging to members that assist lime customers and inform the general public about lime products and their uses. A list of pertinent Web sites follows.

Limestone and Dolomite

Robert C. Freas, John S. Hayden, and Charles A. Pryor Jr.

Limestone and dolomite constitute a group of raw materials commonly referred to as carbonate rocks. They represent the basic materials from which cement, lime, most building stone, and a significant percentage of crushed stone are produced. Carbonate rocks, and their derived products, are used as aggregates, fluxes, glass raw material, refractories, fillers, reactive agents in sulfur-oxide removal, abrasives, soil conditioners, and in a variety of other market applications, many of which are covered in this edition.

Carbonate rocks form about 15% of the earth's sedimentary crust and are widely available for exploitation. Found extensively on all continents, they are quarried and mined from formations that range in age from Precambrian to Holocene. Reserves of carbonate rock are large and will last indefinitely, although high-purity deposits may be absent or have limited availability in certain states and regions.

Limestone and dolomite are so useful and so abundant that in 2002 about 1.6 billion t were produced in the United States. In fact, about 71% of all stone quarried or mined in the United States was carbonate rock. Sand and gravel was the only mineral commodity produced in greater quantity.

This chapter is an overview of carbonate rocks and their composition, distribution, production, and uses. The literature on limestone and dolomite resources of the United States and Canada is so vast and diverse that one can easily become mired in print. The authors have tried to list those references that are easily accessible and serve as a starting point for more intensive study. Additionally,

the selected references on limestone and dolomite resources in Canada and the United States reflect the effort to be selective rather than exhaustive and to direct the reader to the best sources of detailed information. The reader is also referred to other chapters in this volume that provide additional information on limestone and its uses, including the chapters on Lime and various chapters on Construction Uses.

GEOLOGY

Mineralogy

Limestone and dolomite are the principal carbonate rocks used by industry. Limestones are sedimentary rocks composed mostly of the mineral calcite (CaCO_3), and dolomites are sedimentary rocks composed mostly of the mineral dolomite ($\text{CaCO}_3 \cdot \text{MgCO}_3$). Aragonite (CaCO_3), which has the same chemical composition as calcite but a different crystal structure, is economically important only in modern deposits such as oyster shells and oolites. Aragonite is metastable and alters to calcite in time. Some other carbonate minerals, notably siderite (FeCO_3), ankerite ($\text{Ca}_2\text{MgFe}(\text{CO}_3)_4$), and magnesite (MgCO_3), are commonly found associated with limestones and dolomites but generally in minor amounts.

Because of their similar physical properties, the carbonate minerals are not easily distinguished from one another. Specific gravity, color, crystal form, and other physical properties (see Table 1) are aids to mineral identification if the rock is relatively monomineralic and compact. Further information on the chemical,

Table 1. Physical properties of some common carbonate minerals

Mineral	Physical Properties	Common Color
Calcite (CaCO_3)	Hexagonal crystal system, commonly good rhombohedral cleavage. Mohs hardness, 3; specific gravity, 2.72.	Colorless or white but may be other colors because of impurities
Dolomite ($\text{CaCO}_3 \cdot \text{MgCO}_3$)	Hexagonal crystal system, commonly good rhombohedral crystals with curved faces. Mohs hardness, 3.5–4.0; specific gravity, 2.87.	White or pink
Aragonite (CaCO_3)	Orthorhombic crystal system. Mohs hardness 3.5–4.0; specific gravity, 2.93–2.95.	Colorless, white, or yellow, but may be other colors because of impurities
Siderite (FeCO_3)	Hexagonal crystal system, commonly distorted rhombohedral crystals. Mohs hardness, 3.5–4.0; specific gravity, 3.7–3.9.	Brown or black
Ankerite ($\text{Ca}_2\text{MgFe}(\text{CO}_3)_4$)	Hexagonal system, commonly rhombohedral crystals. Mohs hardness, 3.5–4.0; specific gravity, 2.9.	White, pink, or gray
Magnesite (MgCO_3)	Hexagonal, usually in granular or earthy masses. Mohs hardness, 3.5–4.5; specific gravity, 2.96–3.1.	White or yellowish but may be other colors because of impurities.

mineralogical, and physical properties of carbonate minerals can be found in Graf and Lamar (1955) and Tucker and Wright (1990).

The rate of solubility of the different carbonate minerals in dilute hydrochloric acid is perhaps the most useful technique to identify them in the field. Calcite is much more soluble in dilute acid than dolomite; hence, if a fresh rock surface is etched, the amount of dolomite left standing in relief can be estimated using a hand lens. Some staining techniques are based on differences in solubility of the carbonate minerals (in decreasing order of solubility: aragonite, calcite, and dolomite). These staining techniques are useful in the laboratory but have limited application in the field (Friedman 1959; Warner 1962). Thin-section staining is particularly effective in the laboratory (Dickson 1965, 1966).

The x-ray diffractometer is commonly used in the laboratory for determining carbonate mineralogy of bulk samples. Cullity (1956), Azaroff and Buerger (1958), Gulbrandsen (1960), Graf and Goldsmith (1963), Muller (1967), and Runnells (1970) describe techniques for determining calcite and dolomite ratios or the percentage of these minerals based on comparison of their diffraction intensities with those of known standards.

Thin-section analysis may be a helpful adjunct to binocular examination of carbonate rocks. Although it is difficult to distinguish between calcite, dolomite, and ankerite in thin section unless staining techniques are used, identification of other minerals, types of carbonate grains, fabrics, textures, and structures is sometimes facilitated by this method (see also section on Physical Properties in this chapter). Appropriate parts of Carozzi (1960) and Hatch and Rastall (1971) introduce microscopic investigation of carbonate rocks, as does the review by Gubler et al. (1967), and Adams and MacKenzie (1998). Good references for assistance in identifying fossils and fossil fragments in thin section are Horowitz and Potter (1971) and Scholle (1978).

Color, an important property of carbonate rocks, can be a rough guide to purity, but it also can be misleading. Only a small amount of noncarbonate material is necessary to produce a marked change in color. The famous building stone called Indiana Limestone, for example, with its distinct gray and buff colors, commonly contains less than 0.2% Fe_2O_3 (iron oxide). Carthage Marble, a fossiliferous dimension limestone from Missouri in shades of gray, generally has a total iron and aluminum oxide content of less than 0.2%. Limestones in shades of gray or green generally indicate the presence of minerals containing iron oxides or carbonaceous matter. As the state of oxidation increases, the colors change to yellows, browns, or reds. A color reference chart is useful in maintaining uniformity of rock descriptions, and one of the most useful is available from the Geological Society of America (Goddard et al. 1963).

Impurities in carbonate rocks vary considerably in type and amount but are important from an economic standpoint only if they affect the usefulness of the rock. Generally, the two most important considerations of each impurity are how much is present and how it is distributed. A considerable amount of some impurities is tolerable in carbonate rock for some uses if the impurity is disseminated throughout the rock. But if the impurity is concentrated in laminae, it may form planes of weakness that seriously affect the performance of the rock.

Clay is perhaps the most common impurity in carbonate rocks. The clay minerals, mainly kaolinite, illite, chlorite, smectite, and mixed-lattice types, may be either disseminated throughout the rock or concentrated in laminae or thin partings. The basic molecular building blocks of clay minerals are silica tetrahedra (a silicon atom and four oxygen atoms) and alumina or magnesium octahedra (an aluminum or magnesium atom and six hydroxyl ions). Other

chemical elements are incorporated into the structure, however, so it is difficult to determine the type of clay mineral by chemical analysis alone. If clay mineral identification is important, other analysis techniques such as x-ray diffraction, differential thermal analysis, and electron microscopy can be used. The clay chapters of this volume give a comprehensive review of clay minerals.

Chert is another common impurity in carbonate rocks and can be disseminated as grains throughout the rock or concentrated in nodules, lenses, or beds. It is composed mainly of very fine grained quartz (SiO_2) that may appear under the microscope as minute sub-equant crystals, usually 1 to 10 μm in diameter (microcrystalline quartz), or as radiating fibers (chalcedonic quartz). Chert easily incorporates impurities, including water, into its structure so that it can be found in almost all colors; its surface texture can range from dense or porcelainous to porous or earthy. Dense cherts have a Mohs hardness of 7 and high impact toughness, which make them particularly abrasive to crushers and other processing equipment. Porous cherts, mainly because of their large surface area available for chemical reaction and moderate solubility in alkalies, are considered deleterious components in aggregates used in concrete. Dunn and Ozol (1962) give comprehensive coverage of the deleterious properties of cherts.

Silica is also found in carbonate rocks as discrete silt- or sand-size grains of the mineral quartz. These grains may be disseminated throughout the rock or concentrated in laminae and beds. Detrital limestone especially may contain a considerable percentage of quartz silt and sand. These grains can act as the nuclei for coated carbonate grains, such as some oolites and pisoliths.

Finely disseminated organic matter is a common constituent of limestones and dolomites and can give the rock a pronounced brown or black color. Bituminous material, an organic derivative of petroleum and residue of former pore fluids, can be present in sufficient quantity to make the rock undesirable for some uses.

Thin-section and insoluble-residue studies reveal trace amounts of a wide variety of other minerals in most carbonate rocks. Although these trace minerals may affect the economic usefulness of rocks used for chemical purposes, such as glass manufacture, they have little effect on rocks used principally because of their physical properties, as in construction materials.

Origin

Most limestones of economic importance were partly or wholly biologically derived from seawater and accumulated in a relatively shallow marine environment. The obvious skeletal material in limestones speaks of a biologic origin, but even nondescript, fine-grained material may derive from the life of organisms. Pellets in many instances are fecal material, and silt- and clay-size particles may be aragonitic-sheath crystals released upon the death of algae. Oolites, which in the past have largely been thought to be the inorganic accumulation of calcium carbonate around a nucleus, may also depend in part on algal activity.

In some places, lime-secreting organisms such as corals, calcareous algae, and mollusks erect large, wave-resistant structures called reefs. The biologically active parts of these structures are generally near the edge of shallow marine shelves where upwelling currents supply nutrients for the growth of the organisms. In other places along such shelves, small skeletal particles or other material can become coated by concentric layers of calcium carbonate to form oolites. Oolites develop best in the high-energy zone of shelves where water currents agitate the grains, and as the oolites build up the y form elongate lenticular bars that nearly reach the water surface. Very fine grained carbonate muds (micritic limestone) derived from the comminution of coarse skeletal material

or precipitated directly from seawater, accumulate in low-energy environments such as lagoons or deep water.

The depositional environment is significant because it determines the size, shape, purity, and other economically significant characteristics of the carbonate rock deposit. Limestones that form in high-energy zones generally contain little noncarbonate material and hence may be the source of high-purity carbonate material. Micrite, which accumulates in zones of low energy, is more likely to be diluted by clay and silt-size noncarbonate material.

Carbonate sediments are highly susceptible to postdepositional alteration and modification. The origin of dolomite is especially significant to the geologist. Although some dolomite may be precipitated directly from seawater, most dolomite is a result of the alteration of calcium carbonate sediments or rocks by hypersaline brines. Good examples are the almost-pure dolomite Silurian reefs in northern Illinois, Indiana, and Ohio, and in southern Michigan.

The depositional environment and postdepositional history of carbonate rocks are best understood by studying modern carbonate deposition. The general reviews by Baars (1963), Ginsburg et al. (1963), and Milliman (1974) are good references for this information. For further information on locations and distributions of modern carbonate sediments, the summaries by Graf (1960a, 1960b, 1963) are useful; the comprehensive discussions of the origin and occurrence of carbonate rock in the papers compiled by Jordan (1978) and Scholle, Bebout, and Moore (1983); in the book by Wilson (1975); and the reviews of limestone by Sanders and Friedman (1967) and of dolomites by Friedman and Sanders (1967) fill the gaps of the other coverages. Tucker and Wright (1990) provide good coverage of carbonate sedimentology.

Classification

The explosive growth in the study of modern carbonate sedimentation from the late 1950s to the present has had a notable effect on carbonate rock classification. Numerous classification schemes have emerged based on this new-found information, such that carbonate rock descriptions are now more explicit and more conducive to genetic interpretation than ever before.

Many aspects of carbonate rocks can be used as the basis of a classification scheme, but perhaps the most useful are composition and texture. Composition can be thought of in terms of mineralogy, types of fossils or grains, or chemical constituents. Texture refers to both depositional and postdepositional features such as relative proportions of framework grains and lime mud, grain size, cement, and pores.

Carbonate rocks are rarely monomineralic in nature; thus, a mineralogical classification of these rocks needs to consider variation in amounts of calcite, dolomite, and noncarbonate materials (see Figure 1). Such a classification is useful in rock descriptions, especially when combined with textural parameters, but it commonly is not sufficient for industrial purposes. Although limestone and dolomite can be used equally well for many purposes, certain uses have special chemical requirements. These special requirements are stated in terms of chemical composition rather than mineralogical composition and specify the quantity of CaCO_3 (or CaO , calcium oxide) and MgCO_3 (or MgO , magnesium oxide) or both in the rock along with the maximum percentage of impurities that can be tolerated. A practical chemical classification considers that ultra-high calcium limestone is more than 97.5% CaCO_3 , high-calcium limestone is more than 95% CaCO_3 , high-purity carbonate rock is more than 95% combined CaCO_3 and MgCO_3 , and high-magnesium dolomite is more than 43% MgCO_3 (theoretically pure dolomite is 45.7% MgCO_3).

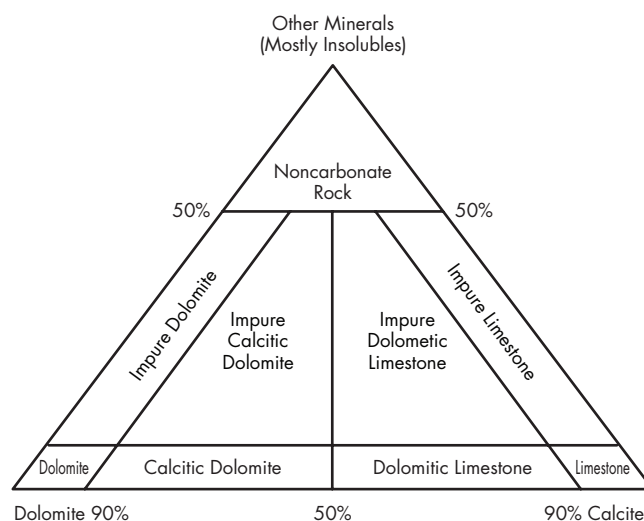

Figure 1. Mineralogical classification of carbonate rocks

A textural classification as well as a mineralogical classification is fundamental to geologic studies to determine the origin of carbonate rocks. One such classification by Leighton and Pendexter (1962) considered that most limestones can be characterized by the types and relative amounts of four textural components: grains, lime mud (micrite), cement, and pores. The ratio of relative proportions of grains to micritic material, which is the basis of their nomenclature system (Table 2), gives some indication of water turbulence because muds cannot be deposited in areas with strong bottom currents. Other classifications, such as the ones by Folk (1962; see Table 3) and Dunham (1962; see Table 4) make use of framework grains to mud ratios and have practical applications.

Dolomite presents a special problem in classification and may require separate handling from limestone. The textural classification can be used for secondary dolomite if the original depositional texture is preserved. Some dolomites, however, show only faint traces of original texture, called ghosts or relics, and others may have had their original texture completely obliterated. For these cases, and for dolomite of primary origin, a classification based on crystal size may be required.

Distribution of Deposits

Carbonate rocks have been deposited from Precambrian to Holocene time, and although they compose only about 0.25% of the volume of the crust of the earth (Parker 1967), they comprise about 15% of the sedimentary rocks. In 2002, limestone and/or dolomite were quarried or mined in all of the 50 states except Delaware, Louisiana, New Hampshire, and North Dakota; they were mined in all Canadian provinces except Saskatchewan.

Because carbonate rocks are widely distributed and differ in their geologic characteristics, each deposit must be considered on its own attributes. The best source of information for carbonate rock deposits is the state geological surveys, or their equivalents. Most state publications are oriented toward aerial geology, commodities, or the two combined, rather than uses or methods. The U.S. Geological Survey (USGS) publishes information on limestone and dolomite. The annotated bibliographies of Gazdik and Tagg (1957) on high-calcium limestone deposits and of Davis (1957) on some high-magnesium dolomite deposits are helpful guides to the older literature, as is the report on high-grade

Table 2. Classification of limestone according to the scheme of Leighton and Pendexter (1962)

Grain: Micrite Ratio	% Grains	Grain Type					Organic Frame Builders	No Organic Frame-Builders

dolomite deposits by Weitz (1942) and a more recent report by Freas and Horne (1982).

Although high-purity carbonate rock deposits are not overly abundant, they are by no means rare. All of the states except Delaware, Hawaii, Louisiana, Mississippi, New Hampshire, and Rhode Island, and all of the Canadian provinces, report potentially commercial deposits of high-calcium limestone or high-magnesium dolomite. A complete list of publications is available on the Web sites of all the state geological surveys; these Web sites are given later in this chapter and in the bibliography. Twenty-one of the 31 Mexican states produced high-calcium limestone or high-magnesium dolomite in 2000, and 5 of the Canadian provinces have commercial production of high-calcium limestone. Because deposits are present, however, does not necessarily mean that they can be exploited. In many areas, competition is intense for potential mineral lands for construction sites, recreation areas, nature preserves, and highways; even nature has its own requirements for flowing streams and soil development. Society has also imposed environmental controls, now firmly established in state and federal statutes, which prohibit or restrict mineral production in areas where it might significantly affect the quality of the environment.

Exploration

Exploration for limestone and dolomite in North America is largely the detailed examination of known deposits. Because most limestone is a sedimentary rock, it occurs in strata generally of consid-

erable extent. Some data on chemical composition and physical characteristics are available for most such strata in the published reports or files of state, provincial, and national geological surveys. Exploration for a new limestone deposit, therefore, in most instances begins with a search of these records to find the locations of deposits that satisfy the various economic factors, and proceeds to a sampling program of favorable deposits. Geophysical techniques, if used at all, are performed to determine the thickness of overburden. Geochemical techniques are not used.

All aspects of exploration are important, but the one most likely to be slighted is sampling. Yet it determines the validity of further study and may become the basis for hundreds of thousands and sometimes millions of dollars' worth of developmental work. The goal of sampling must be the accurate representation of the limestone deposit. The most common sampling methods are coring, rock biting, and surface (ledge) sampling, and the choice among these depends on such matters as the geology of the deposit, the proposed use of the material, and the availability of equipment.

Special care should be taken when sampling weathered outcrops. In humid regions, the surface layer of a carbonate rock can be leached of calcite and dolomite and hence be less pure than the rest of the unit. On the other hand, in arid and semiarid regions, where evaporation exceeds precipitation for long periods of time, the surface layer may be enriched in calcite and dolomite. Thus, if surface samples must be taken under these conditions, the geologist should be aware of a potential bias.

Coring

Coring is generally the best method of exploring a new deposit. A single core may not always be more representative than a section sampled in a quarry or in a natural exposure, where some judgment may be used as to what is representative, but cores taken on a grid pattern constitute a more representative and unbiased sample of a deposit than an equal number of surface sections. Coring avoids contamination by soil and weathered material, and disproportionate sampling of different parts of a single unit, yet retains the surface material that may have worked downward into solution cavities.

Initial drilling is generally widely spaced, both to help locate a potential deposit and to determine its potential size. Once an apparently large and suitable deposit is discovered, it should be drilled in a more or less regular pattern. The core grid and type of drilling depend largely on the proposed use of the limestone, although other factors such as the homogeneity of the deposit, geologic complexity, topography, and cost of drilling are significant. In areas of steeply dipping strata, the grid spacing must take into account whether vertical or inclined drilling will be used. If the stone is to be used as cement raw material and the magnesium content of the rocks is believed to be marginal and unpredictable, no greater than 30-m centers would be required. If the deposit is relatively homogeneous in one direction and not in another, a rectangular rather than a square grid might be used. If the stone is to be used as aggregate and is relatively uniform in other deposits, generally only a few cores need to be taken in several hundred hectares. For most deposits of flat-lying strata in which the chemical composition of the rocks is important, cores should be spaced on 30-m centers until a pattern of uniformity indicates that the spacing can be increased safely. The authors know of one lime company, quarrying in a structurally complex area of Pennsylvania, that found coring on 15-m centers necessary for adequate quality control.

For most limestone exploration, a BX core (4.13 cm in diameter) suffices, but if physical tests are required, a core of larger diameter must be used. NX core (5.4 cm in diameter) is adequate for chemical analyses and limited physical testing but too small for some physical tests. If the core is stored for a significant period of time, it may be necessary to use plastic or wooden core boxes rather than the common corrugated cardboard boxes normally supplied by the core drilling contractor (Figure 2).

Each common physical test of rock used for aggregate requires about 5 kg of rock. Tests for absorption, abrasion, and soundness require more than 14 kg of rock. Testing stone for use as highway materials (ASTM 2004, Volume 04.02; AASHTO 2004) requires a minimum of 23 kg of rock. Highway commissions in some states do not perform physical testing of cores and accept only ledge samples. Testing agencies in other states will run physical tests on cores.

Rock Bitting

Used alone, drill cuttings are probably the least reliable samples in exploration, but if used to supplement cores or information obtained from nearby quarries or outcrops, they are an inexpensive, rapid method of acquiring much information. If the drilling is done in a carefully cased hole to prevent contamination by overburden, if the cuttings are collected carefully, and if the geologist is experienced in interpreting well cuttings, these samples can be as reliable as core and surface sampling for some purposes. In fact, the percussion air drill is probably the fastest and least expensive method for preliminary sampling.

Because of the large amount of drilling for oil and gas during the past few decades, cuttings of thousands of wells are on file in government and other sample libraries. Although not intentionally

Figure 2. NX core being placed in a plastic core box

so, these cuttings constitute the largest exploration program for industrial minerals ever undertaken. Cuttings cannot be interpreted properly unless the interpreter understands drilling techniques, and the best interpretation of the well cuttings requires considerable well-site experience. In addition, the explorationist should be skeptical of these cuttings without prior knowledge of the drilling conditions and the competency of the personnel logging samples from these wells. Stein and Starkweather (1996) is a good reference on drilling and coring.

Surface Sampling

Chip samples taken carefully on a quarry face can provide a good representation of the limestone deposit. The geologist should first inspect the quarry face, divide the face into units of uniform lithology, and then mark tops of units with paint or flags. Thick homogeneous beds should be arbitrarily subdivided, so that no sample is more than about 1.5 m thick. Starting at the base of the unit, one should take chips of uniform size as nearly as possible along a selected vertical line to the top of each unit. (The geologist might start at the top and work down, but it is easier to work up than down.) This method of sampling is sometimes called channel sampling. Chip samples should be taken from unweathered surfaces even if the weathered rind must be chipped away. Samples should be washed to remove contaminants such as lichens or soil, but care should be taken not to wash out thin, interbedded shales.

Many channel or core samples weigh 5 to 10 kg, and this amount must be crushed, thoroughly mixed, and quartered several times in the laboratory to reduce the sample to the few grams needed for chemical determination.

EVALUATION AND TESTING

If given sufficient cores or exposures of rock, an experienced industrial minerals geologist can evaluate a limestone deposit largely just by visual inspection, using a hand lens, hammer, and weak hydrochloric acid as the only tools. The geologist can generally appraise whether a stone will make class A aggregate or cement raw material. They may not, however, be able to determine whether the stone is of sufficient purity for other uses. Final evaluation of rocks suitable for aggregate, dimension stone, and similar uses requires physical testing. Rocks used for making lime, cement, or other products that depend on chemical purity should be chemically analyzed.

Table 5. Physical properties of selected carbonate rocks

Age	Formation	Location	Rock Type	Apparent Specific Gravity	Apparent Porosity, %	Compressive Strength, MPa	Modulus of Impact, MPa	Toughness, cm/cm ²	Reference
Miocene	Unspecified	Eniwetok	Limestone (fossiliferous)	2.39	4.0	97.2	16.5	0.4	Blair (1956)

The American Society for Testing and Materials (ASTM) *Directory of Testing Laboratories, Commercial-Institutional* (2005) lists laboratories capable of making chemical and physical determinations on rocks.

Physical Properties

Procedures for physical testing can be obtained from two main sources: ASTM and the American Association of State Highway and Transportation Officials (AASHTO). Both organizations describe explicit procedures, in cookbook fashion, for testing limestone and dolomite. State highway commissions may specify slightly different procedures and should be consulted if stone is to be used as aggregate in those states. In earlier years, several federal organizations developed physical tests for building stone, such as those reported by the U.S. Census Office and the U.S. Bureau of Standards; however, current building-stone testing generally follows procedures outlined by ASTM.

Physical tests are designed to test how well a rock will perform for a particular use. As might be expected, many tests have been developed corresponding to the many uses for which the carbonate may be designated. Table 5 shows selected physical properties of carbonate rock. The *Handbook of Physical Constants* (Birch et al. 1950) and a book by Barksdale (1991) describe a large number of physical properties of limestones and other rocks. These references contain data on bulk density, compressive strength, compressibility at high and low temperature, dielectric constant, electrical resistivity, porosity, thermal conductivity, thermal expansion, and other properties that are especially useful to the geophysicist. Manger (1963) published a tabulation of porosity and bulk density determinations of carbonate rock, as reported in the accessible American, British, German, and Swiss literature.

A great many physical tests of carbonate rock used for aggregate have been performed in connection with state and federal road-building programs, but much of this information is unpublished. Unfortunately, most data from testing of aggregate in the federal highway program have not been tabulated. Marek (1991) gives a

useful overview of sampling and testing principles. Unfortunately, much of that material is dated relative to changing highway construction methods and materials requirements. The International Center for Aggregates Research (ICAR) is now the focal point of current aggregate research. ICAR is a collaborative effort of the University of Texas at Austin and Texas A&M University and has very strong ties to the National Stone, Sand, and Gravel Association (NSSGA). ICAR publishes a free reference library of information on their Web site at www.ce.utexas.edu/org/icar. AASHTO, a nonprofit association representing the transportation departments of all 50 states, the District of Columbia, and Puerto Rico, publishes an excellent two-volume book on aggregate material standards (AASHTO 2004).

Through the years, the U.S. Army Corps of Engineers (USACE) has tested carbonate rock from many quarries in the continental United States to evaluate their potential use in constructing locks, dams, and other structures. Technical Report No. 6-370, *Test Data Concrete Aggregates in Continental United States* from the USACE Waterways Experimental Station (1953) gives a summary of this testing, which includes the standard tests for sulfate soundness, abrasion resistance, specific gravity, and absorption. This compilation, which occupies nearly a meter of shelf space, cannot be purchased but is available for inspection at USA CE libraries. Other, more accessible publications that give physical test values and results of USACE extensive research relating to the use of carbonate rock as aggregates in portland cement concrete include one by Curry and Buck (1966). The most current list of USACE publications is available from the Engineer Research and Development Center Professional Library Services, an online library at <http://www.edrc.usace.army.mil/library/publications>.

Some manufacturers of pulverized limestone, defined as limestone or dolomite having a minimum fineness of 97% passing a 325-mesh sieve, established standards and test methods through the Pulverized Minerals Division of NSSGA. Recommended test methods include those for particle size, pH, dry brightness, water demand, and calcium and magnesium carbonate content.

Petrographic examination of carbonate rock can foretell its physical properties and subsequent suitability for certain uses, but too few people use this method. The definitive reference for this type of applied petrography is ASTM Standard C295, which is based on work from the 1950s. Techniques of petrographic examination and some of its applications can be found in Mielenz (1954, 1955), and Scholle (1978).

Rippability is a physical property of rock that concerns mainly the construction industry. Limestones that are thinly bedded, low in compressive strength, or sufficiently inhomogeneous so as to contain horizontal planes of weakness can generally be ripped easily. Empirical testing by the Caterpillar Tractor Co. (1972) found a relationship between seismic wave velocities and rock rippability: the higher the wave velocity, the more difficult it is to rip the rock.

Various research workers have examined the relationships between different physical and chemical properties of carbonate rocks. These attempts have not met with much success because of the inhomogeneity of the rocks. Further information can be found in Judd and Huber (1961), West and Johnson (1965), Baxter and Harvey (1969), and Barksdale (1991).

Chemical Properties

The chemical and physical properties of carbonate rocks are interdependent. Pure calcite in the form of poorly cemented chalk is not only unique in its low strength and high absorption among the carbonate rocks but is also highly reactive chemically because of the large surface area of its component grains. Pure calcitic marble of the same chemical composition as chalk is relatively strong, unabsorptive, and unreactive. Dolomite that contains quartz sand grains can have the same overall composition as dolomite that contains chert, but its suitability as aggregate differs widely because of the difference in reactivity of the two forms of silica. Processing also affects the degree of fracturing of stone and thus its surface area and chemical reactivity. Therefore, physical and mineralogic descriptions of carbonate rocks are of importance in predicting the chemical properties of the products that may be produced from a deposit.

For some uses of carbonate rocks, chemical analysis may be of little or no help in estimating the suitability of a rock unit; for other uses chemistry is of utmost importance. For example, in stone used for chemical purposes, such as glass raw material, flux, or cement, the percentage of certain elements must fall within specified limits or ranges. On the other hand, the chemical content may or may not be important for stone that is used because of its physical properties, such as aggregate, building stone, or riprap. A thick section of rock that is almost pure dolomite is likely to be well-cemented reefal dolomite, and it can be predicted generally to make good aggregate (Ault 1989). Rock that is pure calcite, however, may be a skeletal or oolitic limestone that is either well cemented or poorly cemented and thus might make excellent or only fair aggregate.

The proportion of alumina (Al_2O_3) and silica (SiO_2) in the rock may be helpful in determining the value of a carbonate rock for a use in which physical properties are important. Most silica in a carbonate rock is likely clay, silt- and sand-size quartz, or chert. For the common clay minerals found in limestones and dolomites, as much as 2% silica may be present for each 1% of alumina. The higher the alumina content, the more argillaceous the sample is likely to be. The alumina content can be multiplied by two to obtain an estimate of the amount of silica tied up in the clay.

The chemical analysis of a carbonate rock is essential for estimating the neutralizing value of agricultural limestone, which is usually expressed in terms of calcium carbonate equivalent (CCE).

Pure calcite ($CaCO_3$) is assigned a CCE value of 100. Pure dolomite ($CaCO_3 \cdot MgCO_3$) has a theoretical CCE value of 108.6; that is, it is 8.6% more effective than pure limestone as a neutralizer. Such interpretation assumes that a molecule of $MgCO_3$ with a molecular weight of 84.32 is as effective a neutralizer as one molecule of $CaCO_3$ with a molecular weight of 100.09. Thus, a given weight of $MgCO_3$ is 1.19 times as effective as the same weight of $CaCO_3$. Because of differences in solubility, however, a dolomitic liming material will take longer to neutralize a given amount of acid than a pure limestone, even though the CCE of both is the same. Goodwin (1979) is a useful guide to selecting agricultural limestone materials, as is information available from several state agency Web sites (see Additional Resources section in this chapter).

Many published chemical analyses of carbonate rocks show the varied compositions of limestones and dolomites (Clarke 1924; Graf 1960b; Siegel 1967), but these may not always be typical of the formation from which they were taken. Most sedimentary carbonate rocks vary in their impurities—including clay minerals, resistant minerals such as quartz, and organic material—because they were deposited in different environments. In addition, the rocks have evolved chemically as well as physically during compaction, dehydration, and lithification. Subsequent processes, including burial and exposure to percolation of water, provide for synthesis of authigenic minerals and alteration, such as oxidation of organic matter. Because of the limited extent of identical environments of deposition and subsequent postdepositional conditions, composition of any given rock unit is likely to be variable. Analyses of many samples taken at different sites are required to reveal the approximate composition of a particular rock unit.

Good sources of chemical data on carbonate rocks are the state geological surveys or their equivalents. Many state surveys have files of chemical data obtained from quarry sampling and coring programs. The USGS has published 1,131 analyses of carbonate rocks from Colorado, Kansas, Montana, Nebraska, North Dakota, South Dakota, and Wyoming (Hill, Werner, and Horton 1967) and 3,585 analyses of carbonate rocks from Alaska, Idaho, Oregon, and Washington (Hill and Werner 1972).

Specifications

Limestone specifications vary with end use of the stone. These specifications can be either physical or chemical, but frequently they include both. Physical specifications such as durability and gradation are more important if the stone is to be used as mined, such as for construction aggregate. Chemical properties are more important if the stone is to be subject to calcination, as in the production of lime or cement. Most industrial and agricultural applications require adherence to both a physical and a chemical specification. For example, glass-batch raw materials might have both a rigid chemical specification and a narrow gradation requirement.

Physical specifications focus on both the natural properties of the rock and the properties imparted during processing. Natural properties are intrinsic, such as hardness, composition, texture, color, porosity, and density, and processing properties are derived from the physical gradations and result from crushing, screening, washing, and air classification. Obviously the results of processing are directly related to the natural characteristics of the stone.

Physical specifications relating to gradation and durability are by far the most common when the rock is used as an aggregate material. These specifications are based on standardized testing and practices developed through ASTM. ASTM-specified grading requirements for coarse aggregate are shown in Table 6. Other related ASTM physical specifications can be found in ASTM 2004 (Section 4—Construction).

Table 6. Grading requirements for coarse aggregates

		Amounts Finer than Each Laboratory Sieve (Square-Openings), wt %

Table 7. Comparison of size gradations no. 8 stone screen size % passing

State Specifications	1 in.	1/4 in.	1/2 in.	3/8 in.	No. 4	No. 8	No. 10	No. 16
ASTM		NA*	100	85–100	10–30	0–10	NA	0–5
Ohio	NA	NA	100	85–100	10–30	0–10	NA	0–5
Indiana	100	85–100	20–60	NA	0–5	0–2	NA	NA
Kentucky	NA	100	85–95	40–65	5–20	0–5	NA	NA

* NA = not applicable.

ASTM standards provide guidelines for both required gradations and test methods employed in evaluating materials for use as construction aggregates. The specific gradation requirements may vary to some degree by individual state as a result of specific regional application or generally accepted practices. As an example, Table 7 compares gradations for an ASTM No. 8 specification with gradation for a No. 8 stone from Ohio, Indiana, and Kentucky.

Although there may be state-to-state modifications or variations in physical gradations of specific stone sizes, most states generally have durability requirements that are fairly consistent across the United States for aggregates for use as highway surface materials. The most common specifications for durability relate to abrasion, soundness, and freeze-thaw, all of which are covered by an ASTM standard procedure. These tests are a measure of the rock's

ability to withstand repeated cycles of weathering and continued impact of traffic. Several states have also included skid resistance for aggregate to be used in surface-course paving and bridge decks. As a consequence, several states have excluded carbonate rocks for these uses because they polish easily.

Frequently, the specifications for rock used in projects not funded by states or the federal government are modified for economic reasons such as lower transportation costs. This type of project could include nonsensitive uses such as subgrade material for driveway or other nonload-bearing purposes. Conversely, a higher transportation cost might be justified to achieve a specific appearance, as in some exposed-aggregate applications where architectural requirements are more important than economic considerations.

Chemical specifications for carbonate rocks generally are industry or application specific. In any consideration of chemical specifications of a limestone or dolomite, it is important to understand that chemical properties are not necessarily related to physical properties. For example, high-purity limestone from the Mosheim Formation in Virginia is very hard, whereas equally pure limestone from the Ocala Formation in Florida is very soft. The marble from the Franklin Formation in New Jersey has both high-brightness and high-carbonate values, yet the dark gray, almost black, marble from Michigan's Dundee Formation has a higher calcium-carbonate value.

Limestone and dolomite specifications can be developed in a variety of ways, including rigid testing and evaluation, mutual consent between the buyer and seller, common practice in an area, or even as a compromise to offset some other item such as high freight cost. A specification may also be written to describe a particular limestone source, such as when the buyer is not sure which components are important for a particular application. In these instances of uncertainty, the final specification results from testing several different limestones; selection is based on best performance.

Some specifications may be unique to a particular industry and require testing properties based on an industry standard or procedure. Thermal decrepitation, odor, taste, and crystallinity are examples of such properties. In some instances, these requirements may be related to a specific company and be unique to the specific application. For instance, when a limestone is used in rice polishing, it may be subjected to a taste test to ensure that the limestone does not impart an unpleasant taste to the rice during polishing.

As noted previously, it is not at all uncommon for a limestone specification to incorporate both physical and chemical requirements. This is particularly true of industrial uses such as glass manufacturing, where limestone is one component of the glass-batch raw materials. In this example, particle size, gradation, chemical degradation, and chemistry are equally important. Additionally, batch-to-batch uniformity of composition, both in chemistry and physical properties, is important and may require statistical process control (SPC). The importance of SPC should not be underestimated. For example, Tier One automotive glass producers require all glass-batch suppliers of raw materials to employ audited SPC in their process technology to qualify as an acceptable vendor. Several manufacturers also require ISO 9000 certification, although this is not consistently applied to the limestone and dolomite industry.

Table 8 shows typical specifications for limestone to be used in glass-batch raw materials. Industry-specific specifications such as those required for limestone or dolomite used in the production of lime or cement, in flue-gas desulfurization, and filler and extender specifications are included in the chapters on these materials. Any industrial or agricultural application, however, can have a unique specification predicated on specific performance requirements. Individual publications on specifications and uses are available at <http://www.nssga.org>.

PRODUCTION AND USES

The USGS reports that 1,130 t of limestone, dolomite, and related materials were sold or used in the United States in 2001 (Table 9) for construction purposes, including the production of lime and cement. As in previous years, carbonate rock was produced in 48 of the 50 states, with only Delaware and North Dakota not reporting any limestone or dolomite production. The top five producing states in descending order were Texas, Florida, Missouri, Illinois, and Ohio. These five states accounted for 40.8% of total U.S. production.

The tonnage is consumed in hundreds of applications, but the predominate markets for limestone and dolomite can be divided

into 9 major categories and 39 primary uses (Table 10). The first five major categories are related to the use of carbonate rocks as construction materials. A total of 430,613,000 t, or 38% of all crushed carbonate rock produced in the United States in 2001 was produced for aggregate markets. Limestone and dolomite thus represent 54% of the total 790 t of an aggregate material sold or used. Agricultural applications consumed 11.7 t of limestone and dolomite, of which agricultural liming materials made up 83% of this category. Chemical and metallurgical uses account for about 99.3 t, or about 8.8% of all the limestone and dolomite produced each year. Tegethoff (2001) gives additional information on the use and applications of limestone.

Special uses cover a host of applications, the largest of which are fillers, extenders, and whitening materials. Because of the unique applications and value of these products, they are covered in a separate chapter. Mine dusting and acid water treatment are a unique category unto themselves. High-calcium limestone (more than 95% calcium carbonate) is used as rock dust in coal mines as an explosion suppressant. This product must contain less than 2% silica and

is normally ground to 95% less than 325 mesh. Limestone or dolomite used in acid-water treatment can be specified with a variety of sizes depending on both the pH of the water to be treated and available residence time. In some instances, limestone may be injected as a 325-mesh powder into a low-pH effluent stream, or it might be used as boulders in acid streams not suitable for continuous treatment with finer-grained materials.

Dimension stone is the one category not included in Table 9. Dimension stone production is closely tied to commercial construction; in 2002 about 1.26 Mt were produced in the United States. Limestone and marble together account for approximately 33% of total U.S. dimension-stone production. Indiana was the leading state in dimension limestone production, and Georgia was the leading state for dimension marble production, followed by Vermont.

When granite production is included with limestone and marble production, the United States is the fourth largest producer of dimension stone in the world. Nevertheless, total U.S. dimension-stone production has historically been one fourth that of Italy and one half that of Spain (Harries-Rees 1991). Italy, Spain, and Greece produce more dimension stone than the United States; each is a net exporter and the United States is a net importer of dimension stone.

Interestingly, dimension stone production is reported in tons, but sales and prices are normally based on the cost per cubic foot. These prices have remained fairly constant over the last several years; increases in profitability realized by producers have come from increases in productivity.

PREPARATION FOR MARKET

Mining

Limestone and dolomite are high-volume, low-value commodities. This segment of the industrial minerals industry is highly competitive and is characterized by thousands of operations serving local and regional markets. Thus a competitive environment dictates that production cost control is the critical element in any stone operation.

Most limestone and dolomite are mined from open quarries, although in many areas economic and environmental considerations favor large-scale production by underground mining. The only carbonate materials not consistently recovered by surface or underground mining are shell products that are dredged from parts of U.S. coastal waterways, and this is coming to an end with increased environmental pressure in conventional areas of shell production.

Surface Mining

The basic elements of surface mining are overburden removal (stripping), drilling, blasting, and hauling ore to the crushing and processing plant. Ultimately the surface mine must also contend with reclamation requirements. The selection of surface mining equipment varies with the particular requirements at each operation, including production capacity required, size and shape of the deposit, haul distances, estimated life of the operation, location relative to urban centers, and other social and economic factors. Other factors that must be considered in surface mining are the value of the products produced, location of competitive operations, and environmental and safety requirements associated with a particular deposit.

Frequently, a surface mine or quarry will contract for the drilling or blasting part of the production cycle. The specialized nature of this aspect of production, combined with the unique regulatory and safety requirements associated with the handling and use of explosives, may make the use of an outside contractor economically attractive, particularly for quarries close to densely populated urban environments. The contractor is responsible for the maintenance of an explosives magazine and all record and reporting requirements and may arrange for seismic monitoring of each blast.

The issue of explosives handling and storage has become much more highly regulated since September 11, 2001, adding considerable incentive to using an outside contractor.

Overburden removal is a key element in the cost of any surface mining operation and consequently its ability to compete with other mines in its market area. For example, if 3 m of overburden must be removed to recover 30 m of limestone, a mine with 15 m of overburden for the same 30 m of rock will not be competitive. If a mine is unique to its particular area, however, a high overburden ratio may be economically justified. Additionally, the production of high-value end products may support mining operations that would not be economical for low-value products. For example, in East Tennessee, as much as 90 m of overburden has been removed from a 30-m-thick, steeply dipping deposit of chemical-grade limestone for use in the production of lime. This high overburden ratio would probably not be justified if this were a conventional aggregate operation.

Underground Mining

In 2002, 83 underground limestone mines were operating in the United States. In 1900, total production of limestone from all underground mines was 95 kt, or 0.37% of the total limestone production. In 1924, production was 520 kt, or 4.5% of the total production. In 1965, it was 31,200 kt or about 6% of the total limestone production. In 2002, it was 60,000 kt or about 5.3% of the total production. Many of the mines are in the Midwest, however, and this reflects the abundance of high-quality limestone in horizontal beds in that part of the country as much as a concentration of population. This distribution pattern will change gradually as more mines are built to serve urban centers (Carr and Ault 1983; Baxter 1989).

The basic operations in underground mining are drilling, blasting, loading and hauling, scaling, and roof bolting. Drilling equipment includes horizontal drill jumbos and downhole track drills. This equipment is generally quite different from that used for surface mining and results in much smaller blast holes and a lower volume of rock pulled with each blast. Other equipment required in the underground mine includes powder loaders, which are used to blow ammonium nitrate-fuel oil mixtures into the blast holes. Scaling rigs, which are used to remove loose rocks from the ribs and roof of the mine, and roof-bolting equipment may also be required in an underground mine.

Most underground limestone and dolomite mines are room-and-pillar-type operations, and many recover rock from both headings and benches. It is not uncommon for an underground limestone mine to have several benches and an overall mine height up to 30 m. Whereas the thickness of the deposit being mined is directly controlled by the thickness of the rock and related roof conditions, it is not uncommon for an individual heading to be 7.5 to 10.5 m high, and in some instances to reach as high as 15 m. Rooms are generally 13.5 to 15 m wide, which, depending on the type of drilling jumbo used, normally can be mined with one- or two-drill setups. A V-type drill pattern is commonly used to maximize the amount of rock pulled with each shot to reduce the number of boots or unbroken rock in the shot face. Scaling is normally required as a safety measure; roof bolting may or may not be required, depending on roof conditions at the individual mine. Loading and hauling equipment may include standard 22 to 45 Mt haul trucks and correspondingly sized front-end loaders. In some mines, the loading equipment may be more typical of underground hard-rock operations, and may include load-haul-dump units or other types of tramming equipment. For more detailed information on both surface and underground mines, the reader is referred to Kennedy (1990), Bise (1986), and Hartman (1992).

Processing

Limestone processing varies with the end product and targeted consuming industry but of necessity includes several basic similarities. These similarities relate primarily to sizing and include crushing and screening. Depending on such factors as the volume of rock processed, type of mine, haulage distance, and surface topography, primary crushing may be done either at or near the mining face or at the primary processing plant. When primary crushing is done in the quarry or mine, the rock is normally reduced to a less than 15-cm diameter and is moved via conveyor to the main processing plant.

Selection of crushing equipment depends on plant size, physical properties of the rock, and the product produced. In general, primary crushing is by a jaw or gyratory crusher, but an impact crusher or other specialized equipment may be used. Several underground limestone mines use Stamler feeder-breakers as the primary crusher, which is a low-profile piece of equipment. Secondary crushing is usually by cone or gyratory crushers, although impact and roll crushers and hammer mills may be used.

Screening is one of the most critical steps in the processing cycle, particularly in the production of crushed stone. The selection from a wide variety of screen types and screen cloth depends on the requirements for the end product. Most screens incorporate some form of inclined vibratory equipment. Screen cloth can range from a rod, a deck, or punctured steel plates for larger product sizes down through woven wire, welded wire cloth, rubber, plastic, and polyurethane for smaller product sizes. Screens must be checked regularly for holes and tears because oversized material can quickly contaminate a significant volume of product. Stainless steel is frequently used for the screen cloth to reduce wear and increase screen life.

Quarried stone usually has some moisture associated with it, and, as a consequence, fines may adhere to larger pieces of rock. Many crushed stone facilities include washing equipment in the production line to remove these fines and thus ensure gradation specifications and the removal of clay or soft shale. Where washing facilities are included in the processing cycle, settling ponds are also required to eliminate the discharge of silt-laden water to neighboring streams. Where stone washing is not practical and when moisture cannot be tolerated in either subsequent processing steps or the final product, a dryer may be required. The dryer is normally installed ahead of the screening equipment. These dryers are usually counterflow rotary dryers that operate at 120°C to 150°C. Fluidized-bed dryers may also be used and are particularly applicable where flash calcination of fines might be a problem.

Limestone and dolomite processing for industrial and agricultural applications may also require air classification and milling equipment, particularly when products are smaller than 10 mesh and must have a clean bottom cut (usually at 100 or 200 mesh). Air classifiers are easily adjusted and have the flexibility to make a wide range of products. Cage mills, roller mills, and ball mills are used in the production of varying particle sizes ranging from 20 mesh to 2 µm. Wet processing is usually required to produce products smaller than 2 µm.

Once processed, the stone products must be stored before shipment. Most crushed stone products are stored in open areas or in a combination of open areas and loading bins. The volume of material produced and the variety of products generally dictate the design of the storage area. In many larger aggregate operations, a series of radial stackers distribute stone from the screening plant. Alternatively, a plant may have several stone bins to facilitate truck or rail loadout. Storage of industrial and agricultural products requires enclosed silos and bins to protect them from moisture and contamination by other products. These bins and associated loadout

devices require positive dust control, including adequately sized baghouses. They may also include pneumatic conveying equipment or bucket elevators in the product-handling system.

Programmable controllers or computers are finding increased use in the processing of limestone and dolomite. As process plants become larger and more complex, computer-controlled processing systems are an invaluable tool in achieving improved production efficiencies and improved product quality. This equipment can be incorporated into the statistical process-control program of the plant and can be interactive with loadout and scale computers. Where interactive systems are used, they can provide on-line inventory control, bills of lading, and input directly from loadout scales to computer-generated invoicing. Several software packages available today are particularly well adapted to aggregate operations. A useful reference is the NSSGA publication *Guidelines for the Successful Automation in the Crushed Stone Industry*, which can be supplemented with the proceedings from the NSSGA annual Automation Conference (NSSGA 1990). The annual proceedings can be purchased through the NSSGA Web site (<http://www.nssga.org>).

Transportation

Transportation is a major factor in the delivered price of limestone and dolomite products. In very general terms, the lower the value of the processed product, the shorter the distance it can be transported. Stated another way, construction aggregates are less likely to move long distances to the marketplace than are 2-µm carbonate filler/extender materials. In many places, the cost of transportation equals or exceeds the free on board (f.o.b.) plant value of the stone. Thus, limestone and dolomite aggregates generally are marketed locally.

In the limestone and dolomite chapter in the 6th edition of *Industrial Minerals and Rocks*, it was reported that trucking accounted for 82% of the transportation of limestone and dolomite products in the United States. The remainder of the material was transported about equally by rail or waterway. This distribution has not changed appreciably in the last 10 years; however, many factors related to the cost of transportation have changed. Both rail and trucking rates have been deregulated, and competition functions openly in the marketplace. As a consequence, it is frequently possible for a stone processing company to negotiate rates for specific jobs or contracts. This competition also has fostered a number of unit train and intermodal transportation arrangements that have allowed aggregate products to be delivered to more remote locations than previously thought possible.

In evaluating the cost of trucking limestone and dolomite products, the trucking costs associated with aggregate and crushed stone materials must be considered separately from the cost of transporting higher value industrial and agricultural products. The specifics of trucking vary from area to area; however, in very general terms, approximately half the trucking of crushed stone is done by a contractor purchasing and using the aggregate as opposed to owner/operators or commercial haulers. Many state and local governments also have their own trucking equipment and can be grouped with those contractors hauling for their own purposes or jobs. For them, the actual cost of trucking is extremely difficult to determine because each values and costs transportation somewhat differently. For owner/operators or contract haulers using open dump trucks for hauls of less than 40 km, a charge of \$0.06 to \$0.10 per metric ton-km is not uncommon. These rates are subject to negotiation and may be cut significantly on very large construction projects; they also do not include fuel surcharges.

In many places, trucking of industrial and agricultural products is handled differently from the hauling of limestone and dolomite aggregates. The equipment normally used includes pneumatic

tankers, bottom-dumping grain trucks, and vans and flatbeds for bagged products. Where bottom-dump grain haulers can be used, back-haul freight rates may be possible, thus allowing the producer to reach customers whose geographical location is far more remote than would otherwise be economical with normal tariff rates. Contamination by foreign matter is a major concern for many industrial customers; consequently, some carbonate producers operate their own equipment or contract with a specific hauler for dedicated equipment. Even then, it may be necessary to use rigorous clean-out procedures to prevent contamination, particularly when bulk micrometer-sized product is being trucked. Because of the specialized nature of equipment used for industrial and agricultural purposes, trucking rates tend to be slightly higher than those for aggregate products and may be in the \$0.10 to \$0.20/t-km range. These rates may also be subject to negotiation when a consistent haul can be established and several units can be dedicated to a specific customer.

Railroads continue to be a major factor in the transportation of limestone and dolomite products, whether aggregate materials or industrial and agricultural products. For aggregates, rail movement may use intermodal facilities at the receiving end where the stone is either transferred to a stockpile or directly to a truck for delivery to the customer. Such facilities are used successfully in selected markets and most recently were employed by one Pennsylvania producer to move aggregates into the Baltimore-Washington market area. On a single line haul with 60 to 90 car unit trains, it is possible to ship aggregate products at a cost of \$0.02 to \$0.06/t-km. In many places, agricultural and industrial customers are large-volume users and require the use of covered-hopper equipment. In these instances it is possible to negotiate very favorable rail freight rates if a single-line haul can be used. The negotiation of favorable rail rates, however, becomes far more difficult when two or more rail lines are involved and when short-line rail carriers impose switching charges. Nevertheless, even in multiline hauls, when the competition is a straight truck movement, the volumes of stone to be transported may justify a very competitive bid from the combined rail effort. The downside to rail utilization is that the railroads have become quite aggressive in assessing service fees, including demurrage, switching fees, and surcharges, which can greatly increase the cost of rail freight.

Waterway transportation continues to handle about the same volume of stone products that it has for the past 10 years. Most of the stone moved via waterway is either construction aggregate or chemical-grade limestone or dolomite used in the production of lime or cement. Transportation by barge normally requires a shipment of 1.4 kt per barge and generally is not attempted on movements shorter than 480 km. Freight quotations of \$0.01/t-km are not uncommon. Barges are not the only means of waterway transportation. Self-unloading ore carriers on the Great Lakes, oceangoing barges, and 27- to 54-kt bulk ship movements on the ocean are also being used to move crushed stone. Ocean freight and Great Lakes shipment rates can be very economical when this mode of transportation is feasible, but it is clearly restricted to large-volume movements.

LEGISLATIVE AND ENVIRONMENTAL ISSUES

Limestone and dolomite producers, along with the rest of the mining industry, are faced with an ever-increasing array of regulatory and environmental legislation. The average U.S. citizen today is far more environmentally conscious than just 10 years ago. As a consequence, the public expects a positive and responsible commitment from the mining industry to environmental, health, and safety concerns. These concerns separate into two basic groups: local community sensitivities, and state and federal mandates.

At the local level, the limestone industry is faced with zoning and community relations requirements, the response to which will dictate the success or failure of each quarry or mine in the years ahead. The response by stone producers must include long- and short-range reclamation plans, aggressive dust and noise control, attention to the aesthetics of plant entrances and other street-appeal items, and a willingness to listen to community concerns. In some instances, restrictions may be imposed on the hours that blasting can take place or on the hours a quarry may operate. One of the major concerns of many communities is the traffic associated with quarry or mine operations. In some places, trucks moving to and from a limestone producer's operations must travel through neighboring residential areas. As a consequence, additional driver safety and courtesy training may be required, and speed restrictions must be aggressively enforced.

State and federal regulations include a number of items of critical interest to the limestone and dolomite industry. As previously noted, reclamation plans may be a critical part of the permit process and should be developed well in advance of mining. In years past, limestone producers could view reclamation requirements as a future issue not needing current planning or engineering. Today, many local communities, and some states, require long-range operating plans that include the reclamation of abandoned areas concurrent with active mining or quarrying. Reclamation plans need to specifically address several items, including long-term land use decisions, health and safety of the community, and elimination of hazardous wastes and other potentially toxic discharges.

State and federal legislation under debate—such as the USACE and U.S. Environmental Protection Agency (EPA) federal wetlands regulations found in Section 404 of the Clean Water Act and associated legislation—will likely have a significant impact on the mining industry. Given the current federal guidelines of no net wetlands loss and the location of many limestone and dolomite resources, conflict appears to be inevitable, although mitigation guidelines can be found at www.mitigationactionplan.gov. Industrial, environmental, and political factions are currently debating the definition of wetlands, and it may be some time before what is and what is not a regulated wetland can be clearly defined. This issue is being litigated in the federal court system, along with questions of jurisdiction between federal and state agencies.

Other critical issues receiving public attention include respirable crystalline silica, storm-water runoff, underground fuel storage tanks, Phase II of the Clean Air Act Amendments of 1990, and potential revisions to the Endangered Species Act. The crystalline-silica issue is of particular concern since silica has been declared a carcinogen by the National Institute for Occupational Safety and Health, and tort claims are being filed even though the specifics for updated Occupational Safety and Health Administration and Mine Safety and Health Administration regulation have yet to be adopted. Several environmental groups and labor unions have challenged current regulations on silica (30 CFR, part 71.01), saying that they are too low. This issue is being both debated and litigated.

Storm-water runoff is another environmental issue that the quarry operator must address. The EPA requires storm-water discharge permits for all mining operations, and requires that the permit applicant consider potential ground water contamination resulting from quarry or mining activities. The NSSGA is working extensively with state and federal regulatory agencies and stone producers to assist in the development of and compliance with these regulations. The NSSGA Web site maintains regular updates on regulatory issues and governmental actions affecting the crushed stone industry (<http://www.nssga.org>).

Federal mandates to eliminate underground fuel storage tanks have been in place for many years. These tanks could potentially contaminate groundwater as they age and develop leaks. Because it is extremely difficult to monitor the integrity of these underground tanks, their removal has been strongly encouraged. In addition, it is also necessary to provide adequate containment structures around surface tanks to mitigate potential environmental issues that could result from a spill.

FUTURE TRENDS

Looking ahead to the next decade, the demand for limestone and dolomite is expected to grow at an average annual rate of about 2.0% to 2.5%. Limestone is the primary raw material for crushed stone, and its demand is expected to match the demand for new construction. In recent years, particular attention has been focused on the nation's deteriorating infrastructure and the need for repair and replacement. Although the specifics of federal funding initiatives may change from year to year, the fact remains that the federal and state governments annually allocate hundreds of billions of dollars to infrastructure repair and replacement.

The demand for chemical-grade carbonate rock used in industrial and agricultural applications is expected to equal, at a minimum, the growth of the U.S. population. In addition, Phase II of the Clean Air Act Amendments of 1990 could greatly expand the demand for both lime and limestone for utility stack-gas scrubbing. Lime is a primary reagent material for both wet and dry scrubbing, and limestone is used in both wet scrubbing and fluidized-bed combustion. These uses are covered in more detail elsewhere in this volume.

Although the demand for limestone and dolomite is expected to remain strong throughout the twenty-first century, the structure of the U.S. stone industry is changing. The most pronounced changes relate to consolidation within the industry and the increasing role played by foreign owners. In the 1990s and continuing into the early years of the twenty-first century, foreign and domestic companies completed mergers, acquisitions, and joint ventures that have resulted in a continuing change in the names on the front gates of many limestone and dolomite operations. Data from the USGS (Tepordei 2002) lists the U.S. top 10 crushed stone producers as follows

1. Vulcan Materials, Birmingham, Alabama
2. Martin Marietta Aggregates, Raleigh, North Carolina
3. Hanson Building Materials—America, Neptune, New Jersey
4. Oldcastle, Inc., Washington, D.C.
5. Lafarge North America, Inc., Herndon, Virginia
6. CSR, Ltd., dba Rinker Materials Corp., West Palm Beach, Florida
7. Cemex, Inc., Houston, Texas
8. Rogers Group, Nashville, Tennessee
9. Florida Rock Industries, Inc., Jacksonville, Florida
10. APAC, Inc., Atlanta, Georgia

A second trend having an increasing impact on U.S. limestone production is the role of imported crushed stone materials. Offshore limestone operations located in Canada, the Bahamas, and Mexico have been able to take advantage of low-cost ocean freight to reach markets along the east, west, and Gulf coasts of the United States. Newfoundland Resources and Mining Company, Ltd., initiated its first shipments of limestone to the United States in May 1990, from a \$30 million plant specifically designed for exporting crushed stone by ship along the eastern coast of the United States. Canada is only one of the countries exporting crushed limestone to domestic U.S.

markets. Martin Marietta's quarry near Freeport, Bahamas, and Vulcan Materials' Mexican imports from the Yucatan have had significant impact on aggregate markets in Florida and along the U.S. Gulf Coast. Martin Marietta's Bahamian quarry ships more 1.4 Mt annually, and Vulcan reports that their operations near Cancun have a capacity of more than 3.6 Mt per year. The efforts of Vulcan Materials, Martin Marietta, and Newfoundland Resources and Mining Company have been directed at the importation of crushed stone for aggregate materials, but they are not the only operations bringing limestone into the United States. On a much smaller scale, white, chemically pure, industrial-grade limestone has also been imported from the Caribbean and China for use in filler/extender materials. These products, however, have thus far represented only a fraction of 1% of total high-calcium filler/extender material produced and sold in the United States. Additionally, both aggregate and chemical-grade limestone is exported from Vancouver Island, British Columbia, Canada, to Pacific coastal ports.

In summary, limestone and dolomite have been and continue to be one of the most important raw materials in the United States. Demand will increase, albeit at a modest rate, and new uses and applications will be found. But limestone and dolomite will continue to be commodities produced and sold in a highly competitive marketplace. Competitive pressure will dictate that limestone and dolomite producers be attentive to cost control and apply improvements in technology to increase productivity. Producers will also have to adapt to a social and political climate that will demand no deterioration in the environment, and thus costs for limestone and dolomite products will increase.

ADDITIONAL RESOURCES

The Web sites of the geological surveys for each U.S. state and Canadian province offer a wealth of information about limestone and dolomite. The URLs are given in Table 11.

ACKNOWLEDGMENTS

This chapter draws heavily on the chapter in the 6th edition of *Industrial Minerals and Rocks*, written by D.D. Carr, L.F. Rooney, and R.C. Freas. The authors of this chapter updated the data and information and revised selected material while leaving much of the chapter as originally written. Because limestone and dolomite are the basic raw materials of a large segment of the construction industry, the majority of material presented in the 6th edition remains current.

Lithium Resources

Ihor Kunasz

INTRODUCTION

The second half of the 20th century saw a dramatic shift in lithium carbonate (and some lithium chloride) production from the usual pegmatite sources to brines. Today, all lithium carbonate, which is the basis of various downstream lithium chemicals, comes from the brines of the Salar de Atacama, Chile, and Clayton Valley, Nevada (United States). Lithium chloride is also produced from the Salar del Hombre Muerto, Argentina. Various other salars and playas such as those of China, Bolivia, Argentina, and Tibet are being evaluated for future lithium chemical production. The industry was once dominated by two major U.S. producers, until a third producer from Chile started production of various salts, including lithium carbonate. This shift in sources led to the shutdown of both U.S. pegmatite operations. Australia, Canada, and Zimbabwe have continued to supply lithium mineral concentrates for the ceramic and glass industry and other applications. Minor producers in Brazil, Portugal, Russia, and the People's Republic of China mine various lithium minerals. One new U.S. supplier of lithium chemicals came on stream using the depleted lithium hydroxide government stockpile.

When it was first recognized, lithium was an oddity that became an important commodity owing to its unusual properties. In 1854 in Germany, R. Bunsen and A. Mathiessen used an electrolytic process to prepare lithium as a free metal from molten lithium chloride. They prepared lithium carbonate, lithium chloride, and then lithium metal from zinnwaldite, a lithium-bearing mica. Lithium-bearing minerals were sometimes used as exotic additives to ceramic compositions.

Not until World War II were the special properties of lithium compounds fully investigated and exploited. A compact, lightweight source of hydrogen was needed for use in emergency-signaling balloons. Lithium hydride was found to be ideal for this purpose. Lithium was also used in alkaline batteries in submarines. Later, greases containing lithium stearate were found to lubricate at both very high and very low temperatures. For the first time, the same grease could be used for multiple purposes over a wide range of operating conditions.

With rocketry came the search for materials that could withstand the extreme temperatures of high-speed travel through the atmosphere. A ceramic composition containing lithium was developed that expanded very little and resisted cracking during rapid extreme temperature change. This lithium-containing material *pyroceram* was the forerunner of modern glass-ceramic cookware

that resists thermal cracking. Perhaps the most recognized application is CorningWare, in which lithium imparts a negative coefficient of expansion when heated, which allows the ceramic to be used from refrigerator to oven without shattering.

In 1953, the Atomic Energy Commission (AEC) required large amounts of lithium hydroxide from which the lithium-6 isotope was separated and reserved for use in producing the hydrogen bomb. For about 5 years, the government was the largest consumer of lithium. After the AEC contracts expired in 1960, the lithium industry, faced with vast overcapacity, sought desperately to develop some commercial markets. Though not an overnight success, it soon became a firmly established supplier to basic industries such as ceramics, lubrication, aluminum reduction, and pharmaceuticals. If certain technical issues are resolved, thermonuclear fusion, which requires lithium as the primary fuel, could solve much of the world's energy requirements.

Today, even though lithium products are widely used in households, factories, and laboratories, lithium's presence often goes unrecognized. Lithium may be as close to the average person as a medicine chest, a television, a swimming pool, or a calculator. Lithium is found in minerals, clays, and brines in various parts of the world. High-grade lithium ores and brines are the present sources for all commercial lithium operations. Economical brine sources of lithium were rare until several salars in South America were discovered to contain significant deposits of lithium.

Lithium was first produced from zinnwaldite in Germany. This was followed by the production of spodumene from the Black Hills of South Dakota, where log-sized spodumene crystals were mined. The WWII exploration for strategic elements (titanium, tantalum, and others) resulted in the discovery of the pegmatite fields in North Carolina (Kesler 1961), where two major lithium mineral and chemical production centers developed. During the 1950s lepidolite from Southern Rhodesia (Zimbabwe) was imported for conversion to lithium hydroxide at a Texas plant for producing the hydrogen bomb. After the depletion of the lepidolite, a spodumene zone was outlined, resulting in the production of high-grade spodumene concentrates. Numerous lithium pegmatites were also discovered in Canada. Spodumene concentrates are produced at the Tanco mine in Manitoba. In the 1980s spodumene was identified during tantalum mining and exploration in Western Australia, resulting in the production of spodumene concentrates at Greenbushes.

Lithium chemical production was shifted when the Silver Peak brine deposit, originally evaluated as a potash source, resulted in the unique production of lithium carbonate in 1966. Although lithium had been identified in 1936 in the brines of Searles Lake, California, the lithium diphosphate scale generated during the boron recovery process was considered more of a hindrance than an economic product. Put into production in 1966, the Silver Peak brine was, for almost 20 years, the only brine source of lithium carbonate production in the world. In 1969, the Chilean Instituto de Investigaciones Geológicas (IIG) identified unusually high concentrations of potassium and lithium at the periphery of the Salar de Atacama in Northern Chile (Moraga et al. 1974). After confirming the high concentrations, Foote Mineral initiated a feasibility study in 1975, and the Sociedad Chilena de Litio (SCL) began producing lithium carbonate from the southern sector of the salar in 1986. Several companies attempted to develop the northern portion of the salar. Eventually, Sociedad Química y Minera (Soquimich or SQM) developed the deposit and produced a number of chemicals, including potassium chloride, potassium sulfate, lithium carbonate, and boric acid. From a nonproducer before 1988, Chile has become the world's major supplier of lithium carbonate (Ober 2002).

The Lithium Division of FMC Corporation explored the Salar del Hombre Muerto in the Altiplano of Argentina and produces lithium chloride from the brine via a patented ionic exchange process.

As a result of extensive exploration for brine deposits, prompted by lithium production development in Chile, several chemical-rich deposits were identified and explored in Argentina, Bolivia, the People's Republic of China, and Tibet. The shift in lithium carbonate production from pegmatites to brines closed the two unzoned pegmatite operations of Chemetall Foote Mineral Company and the Lithium Division of FMC in North Carolina. Zoned pegmatites, which contain high-grade spodumene, continue to be important sources of lithium mineral concentrates for the various ceramic and glass industries.

GEOCHEMISTRY OF LITHIUM

Lithium is a silvery-white metal that is slightly harder than sodium but softer than lead. It is the lightest of all the metals, with a density of 0.534 g/cm³, or about half that of water. It has an atomic weight of 6.938, an ionic radius of 0.68 Å, and a charge of +1. Lithium is the third element in the periodic table and the first element in Group I, the alkali metals group. Like the other metals in the group—sodium, potassium, rubidium, and cesium—it is so chemically active that it never occurs as a pure element in nature; it is always bound in stable minerals or salts.

Some lithium compounds show a great resemblance to Group II, the alkaline earth metals. For example, the water solubility of lithium hydroxide is substantially lower than that of other alkali hydroxides. In general, lithium's physical and chemical properties stem from its atomic structure. An atom of lithium consists of a nucleus (three protons and either three or four neutrons) with three electrons orbiting in two shells. The inner shell (the helium shell) contains two electrons and is chemically inert. The outer shell contains only one electron. Lithium, more than any other alkali metal, tends to eject this electron from its outermost shell. The resulting lithium ion carries a positive charge (+1). In solid metal, individual lithium atoms are arranged geometrically in a cubic lattice and can transfer a negative charge from place to place. This electron movement makes lithium metal an excellent electrical conductor.

A Swedish scientist, Johan August Arfwedson, discovered lithium in 1817 in the laboratories of Berzelius. He analyzed the content of a mineral called petalite from Utö Island, Sweden. The results of the analysis left a sizable percentage of the sample's

chemical make-up unaccounted for. Further work resulted in the extraction of a compound with chemical properties, suggesting that an unknown element was present. Since the new element had been found in chunks of petalite, Arfwedson called it "lithium," from the Greek word *lithos*, meaning stone.

The geochemistry of lithium has been extensively studied, and Goldschmidt (1937), Rankama and Sahama (1950), Hortsman (1957), and Cerny (1991) summarized the work.

The distribution of lithium in igneous rocks is controlled by its size and its charge, and by the (MgO+FeO)/Li₂O ratio. In the early stages of crystallization of a magma, that ratio is very large. Consequently, both magnesium and iron are removed by ferromagnesian minerals in preference to lithium, which is then concentrated in the residual magma. The result is an enrichment of lithium in silicic rocks and pegmatites (Strock 1936).

Pegmatites are coarse-grained igneous rocks formed by the crystallization of postmagmatic fluids. Minerals within pegmatites can also form by metasomatism (Jahns 1955). Genetically the pegmatites are associated with neighboring intrusives. Mineralogically, granitic pegmatites contain feldspar, quartz, and mica as the main constituents and a variety of exotic elements such as lithium, beryllium, tantalum, tin, and cesium, which may or may not occur in economically significant concentrations.

Detailed studies by numerous investigators (Cameron et al. 1949, 1954; Hanley, Heinrich, and Page 1950; Jahns 1952, 1955; Page et al. 1953; Norton and Schlegel 1955; Cerny 1991) indicate that many pegmatites exhibit an internal zonal arrangement, with each zone containing a specific suite of minerals. The lithium minerals are usually found in the intermediate zones, and, although as many as 13 zones have been recognized (Cameron et al. 1949), a complete zonal arrangement is rarely found. Zoning of pegmatite bodies has also been observed regionally. The regionally zoned pegmatite sequences exhibit mineral assemblages and complexity according to their respective distance from the granitic bodies to which they are genetically related. Various theories have been proposed for the genesis of pegmatites. Cerny (1991) offered convincing evidence that rare metal pegmatites are essentially magmatic phenomena. Although pegmatites exhibit a broad diversity of paragenetic, geochemical, and structural styles, pegmatites have crystallized from a volatile-rich melt enriched to various degrees in lithophile elements. From a practical exploration standpoint, Cerny concluded that Late Archean and Early Proterozoic fields are possibly the most productive, and that lower amphibole facies of volcano-sedimentary rocks are the main hosts for pegmatites.

Lithium is also found in small proportions in a variety of rocks. The average lithium content of igneous rocks is estimated at about 28 ppm Li. Sedimentary rocks contain an average of 53 ppm Li, and the highest concentrations are recorded in shale (Hortsman 1957). Volcanic rocks, particularly obsidian, contain high concentrations of lithium (Shawe, Mountjoy and Duke, 1964; Price et al. 2000). Unusual amounts of lithium are found in the clay mineral hectorite, which is expandable and belongs to the magnesian end member of the smectite (montmorillonite) group.

Lithium is also present in significant amounts in waters associated with geothermal areas (White 1957) in Iceland (Reykjavik), New Zealand (Waikare), California (Imperial Valley), and Mexico (Agua Prieta geothermal field). Very high concentrations (up to 47 ppm Li) have been recorded in the El Tatio geothermal field, located north of the Salar de Atacama (Ide and Kunasz 1989). It is also associated with certain oil well brines (Mayhew and Heylman 1966). Lithium occurred in higher concentrations in certain desert basin brines of California (Searles Lake), Nevada (Clayton Valley), and Utah (Great Salt Lake), and in a number of salars in Chile (Atacama, Pedernales,

and others), of which the Salar de Atacama is the richest; Bolivia (Salar de Uyuni); Argentina (Salar del Hombre Muerto, El Rincon, and others); Tibet (Lake Zabuye), where natural lithium carbonate was discovered (Holland et al. 1991); and the People's Republic of China (Qinghai Basin).

LITHIUM MINERALS

Although lithium occurs in some 145 minerals, only spodumene, lepidolite, petalite, and some other minerals such as amblygonite and eucryptite have been commercial sources of lithium. Today, the principal sources of lithium ores and chemicals are spodumene and petalite.

Spodumene

Spodumene, a lithium aluminum silicate ($\text{LiAlSi}_2\text{O}_6$), is a monoclinic member of the pyroxene group. It has a very pronounced cleavage plane (110), which results in typically lath-shaped particles on breaking. The color of spodumene is variable, being nearly white in the low-iron variety and dark green in iron-rich crystals. When clear, spodumene is considered a gemstone. Three varieties are known: hiddenite, the green variety from Alexander County, North Carolina, first discovered in Brazil; triphane, the yellow variety also from Alexander County; and the lilac-colored kunzite from the Pala District in California, and in Brazil and Afghanistan.

Spodumene undergoes pseudomorphic alteration to a variety of minerals. Norton and Schlegel (1955) described spodumene replacement by quartz, albite, perthite, muscovite, beryl, amblygonite, apatite, and tourmaline. Weathering commonly alters spodumene to kaolinite and to montmorillonite.

Spodumene constitutes the most abundant commercial source of lithium minerals. Theoretically it may contain up to 3.7% Li, but the actual lithium concentration ranges from 1.35% to 3.56%, probably as a result of sodium and potassium substitution for lithium. Spodumene concentrates typically contain 1.9% to 3.3% Li. Spodumene occurs in many pegmatite belts around the world and was the conventional source of lithium concentrates and chemicals in the United States (North Carolina) until the discovery of brines closed the only two spodumene mines in North Carolina. Spodumene occurs in many countries: Sweden (Utö), Austria (Koralpe), Brazil (Minas Gerais), Argentina, Canada (Manitoba, Quebec, and Northwest Territories), Zimbabwe (Bikita), Democratic Republic of the Congo (Manono and Kittolo), Australia (Greenbushes), the Russian Federation (Chita region), and the People's Republic of China (Altai Mountains).

Lepidolite

Lepidolite is a phyllosilicate with the general formula $\text{K}_2(\text{Li,Al})_{5-6}[\text{Si}_{6-7}\text{Al}_{2-1}\text{O}_{20}](\text{OH,F})_4$. The chemical variability expressed in the formula stems from a structural complexity attributed to a mixture of polymorphs, which include muscovite, lithium muscovite, and polyolithionite (Winchell 1942). On the other hand, Foster (1960) and Deer, Howie, and Zussman (1962) suggested that there is a continuous series between muscovite with a 2M1 structure to lepidolite with 1M, 2M2, and 3T structures. The structural transition takes place when the lithium oxide content in the mica reaches 1.53%.

The lithium concentration in lepidolite ranges from 1.53% to a possible theoretical maximum of 3.6%. In commercial deposits the concentrations are more normally 1.4% to 1.9% Li. In addition to lithium, lepidolites also carry substantial concentrations of rubidium and cesium (Deer, Howie, and Zussman 1962).

The major commercial deposits of lepidolite are in Zimbabwe (Bikita), Namibia (Karibib), Canada (Bernic Lake, Manitoba), Brazil (Minas Gerais), Portugal, and Spain.

Petalite

Petalite, $\text{LiAlSi}_4\text{O}_{10}$, is a monoclinic mineral with a framework silicate structure. Its color is grayish white and more rarely pinkish. It has two cleavage directions, which form an angle of 38.5° . The basal cleavage is perfect.

The theoretical lithium content of petalite is 2.27%. In commercial deposits it ranges from 1.6% to 2.1% Li. Sizable deposits of petalite occur with lepidolite in Zimbabwe (Bikita), Namibia (Karibib), Brazil (Aracuai), Australia (Londonderry), the former U.S.S.R. (eastern Transbaikalia), Sweden (Utö), and Canada (Bernic Lake).

In certain pegmatites there is evidence that petalite alters to a mixture of spodumene and quartz. For the Bernic Lake pegmatites of Manitoba, Cerny and Turnock (1971) described pseudomorphs of spodumene and quartz after petalite, commonly referred to as SQI, according to the following reaction: petalite (spodumene + 2quartz).

Eucryptite

Eucryptite is also a lithium aluminum silicate that is deficient in silica. It has a formula LiAlSiO_4 and can contain 5.53% Li. The only large deposit of eucryptite is found in Zimbabwe (Bikita), where its occurrence with quartz suggests spodumene origin (Westenberger 1963). The grade of the eucryptite is 2.34% Li. Eucryptite has also been reported in Connecticut (Branchville mica mine); New Mexico (Harding mine); Manitoba (Tanco mine); Ontario (Nakima mine); and North Carolina (Foote mine).

Amblygonite

Amblygonite, with the generalized formula $\text{LiAl}(\text{PO}_4)(\text{F,OH})$, is the fluorine-rich end member of a phosphate series and montebrasite represents the hydroxyl-rich end member. It occurs in white to gray masses. Most cleavage planes are pearly; others are vitreous. Amblygonite weathers to earthy apatite, wavellite, and other lithium-deficient phosphates. Although amblygonite may contain as much as 4.74% Li, most commercial ores carry 3.5% to 4.2%. Amblygonite has been mined in Canada, Brazil, Surinam, Zimbabwe, Rwanda, Mozambique, Namibia, and the Republic of South Africa.

Hectorite

Lithium also occurs in significant concentrations in the mineral hectorite, a trioctahedral smectite. The purest deposit is found at Hector, California, where the white clay is exploited for its swelling characteristics in cosmetic applications. The lithium concentration in the hectorite is 0.53% Li. Hectorite has also been identified in Clayton Valley (Kunasz 1970) and McDermitt, Nevada (Glanzman, McCarthy, and Rytuba 1978).

CONTINENTAL BRINES

Lithium is found in commercial quantities in certain continental brine deposits. The brines, volcanic in origin, are present in desert areas and occur in playas and saline lakes where dilute lithium solutions have been concentrated by solar evaporation. In Seares Lake, where production of dilithium phosphate began in 1938, the lithium concentration is 70 ppm Li. In Clayton Valley, Nevada, the lithium concentration in brines varies from 100 to 300 ppm. Lesser concentrations of lithium (28 to 60 ppm Li) are found in the Great Salt Lake of Utah.

Following the discovery of lithium in the brines of the Clayton Valley, Nevada, exploration revealed the presence of lithium in other playas and salars in the world (Kunasz 1994). High concentrations of lithium have been recorded in several salars in Argentina (Salar del Hombre Muerto, 200 to 2,000 ppm Li); Bolivia (Salar de Uyuni,

Figure 1. Idealized cross sections of three basins

100 to 700 ppm Li); Chile (Salar de Atacama, 1,000 to 7,000 ppm Li); Tibet (Lake Zabuye, 700 to 1,000 ppm Li); and the People's Republic of China (Qinghai, 100 ppm Li; Yiliping, 300 ppm; Tajiner, 350 to 400 ppm Li).

Brines are the predominant sources of lithium carbonate in the world today. Much has been done on the chemistry of these brines, revealing that although playas and salars are similar in many respects, they nevertheless exhibit individual characteristics (Kunasz 1980). Lithium-bearing salars or desert basins have the following similar characteristics: they occur within Tertiary or Recent volcanic belts, they are closed structural depressions, and they occur within the desert areas of the earth. These may then be considered the fundamental requirements for the occurrence of economic lithium brines.

The first requirement simply establishes the source of lithium. The volcanic environment supplies the lithium either directly through hot springs or geothermal solutions or indirectly through the leaching of lithium-bearing volcanic or clastic sediments or by the recycling of trapped lithium-bearing solutions. This condition is met by all three major salars: Clayton Valley, Salar de Atacama, and Salar de Uyuni all occur in areas with abundant volcanic rocks. The second requirement provides the necessary mechanism for retaining the dilute solutions introduced into the basin. Strong structural control is evident in Clayton Valley, Nevada, and in the Atacama Area, Chile. Direct structural control is not obvious for the Salar de Uyuni. Finally, all potentially commercial lithium concentrations are the result of concentration by solar evaporation. With the exception of the Imperial Valley geothermal field and oil-field brines where lithium concentrations as high as 280 ppm have been recorded, high lithium concentrations are not primary but secondary phenomena, caused by concentration under proper climatological factors. Although the fundamental character of the salars is similar, cursory examination of the three lithium-rich basins that are described in the following sections reveals great variability in size, surface character, stratigraphy, structure, and chemistry.

The salars or playas fall within three general types, as illustrated in Figure 1. Clayton Valley is the smallest of the three. Its total surface area covers approximately 100 km². The Salar de Atacama basin has an approximate surface area of 3,000 km², whereas the salt nucleus proper covers an area of approximately 1,400 km². The Salar de Uyuni, on the other hand, occupies a very large surface area of approximately 10,000 km², and thus represents the largest such desert basin in the world. The idealized stratigraphic column of each of the three basins indicates significant differences between them as well and reveals their individual historical evolution. Clayton Valley underwent alternating dry-wet climatic cycles under conditions of structural instability. The Salar de Atacama formed under an intense evaporative cycle with associated major subsidence. The Salar de Uyuni appears to have undergone a single evaporitic cycle with little associated subsidence. When the basin surfaces are predominantly composed of silts and clays with some salt incrustation, they are referred to as playas. If the surface is predominantly salt (with or without polygonal cracks), they are called salars (English) or *salar*es (Spanish).

Clayton Valley, Nevada

The Silver Peak playa in Clayton Valley is known to be a complex system (Zampirro 2004), possibly because it has been extensively studied, having produced lithium for some 35 years. It can be considered an intermediate between the Salar de Uyuni and the Salar de Atacama because it incorporates the structural elements of the Salar de Atacama but underwent fluctuating arid and wet climatic cycles. The basin consists of interbedded fine-grained sediments and halite, some volcanic ash layers, and some tufas. This is consistent with the paleohydrologic regimes in the southwestern Great Basin, although obvious breaks such as those reported by G.I. Smith (1966) at Searles Lake have not yet been recognized. Although the halite layers in the section contain large lithium reserves, production comes mainly from an unconsolidated volcanic ash aquifer and additional reservoirs identified by subsequent exploration. Structure maps of the main volcanic ash indicate that some portions of the basin subsided as much as 150 m during sedimentation. Several sources have been identified for the lithium contained in the Quaternary playa sediments (Figure 2) and in the lithium-bearing aquifers (Figure 3):

- Geothermal fluids issuing from faults on the eastern side of the playa; sampling along a fault zone show a substantial lithium enrichment (Kunasz 1970)
- Increased lithium concentrations in the Tertiary lacustrine sediments exposed on the eastern side of the basin compared to the northern sediments (Kunasz 1970)
- Rhyolitic rocks with high lithium contents on the east side of the basin (Price et al. 2000)
- Concentration of lithium in the Quaternary basin by natural solar evaporation

These conditions resulted in the accumulation of lithium-rich sediments and enriched brine in the southeastern portion of the present playa. This sector is the principal source of the brine fed to the 4,000 acres of solar evaporation ponds in which the lithium chloride is concentrated (Zampirro 2004).

Salar de Atacama, Chile

The Salar de Atacama is in northern Chile at an elevation of 2,300 m, where it straddles the Tropic of Capricorn. The basin proper has a surface area of approximately 3,000 km², and the salt nucleus proper covers approximately 1,100 km². The salar is bounded on the eastern

Figure 2. Lithium content (ppm) of surface sediment samples, Clayton Valley, Nevada (A–B sampling location is in Figure 3)

side by Andean Cordillera and on the western side by the Cordillera Domeyko (Figure 4).

The salt nucleus consists almost exclusively of a halite facies with a development of very narrow marginal facies of sulfate and carbonate. The surface of the salar is extremely rugged because of extensive development of polygonal cracks (Figure 5). It is similar in many respects to the Devils Golf Course in Death Valley, California.

During the early exploration phase in 1975, access to the salar was limited to trails and a 37-km gravel road, so much of the geochemical work was conducted by helicopter. Numerous roads have since been built for the two brine operations. The Salar de Atacama basin is a graben in a tectonically quite active area with numerous fault scarps. The extensive thickness of salt in the basin indicates that saturation with respect to sodium chloride was predominant during most of the subsidence history of the basin. No beaches or algal reef complexes are present, which suggests desiccation from a much larger body of water. The ancestral chemical system was probably very high in solutes. The source of the lithium in the basin is volcanic in origin (Ide and Kunasz 1989). It enters the basin from two principal directions. One is from the north where the liquid from the El Tatio geothermal field (with lithium concentrations of 47 ppm) discharges via the San Pedro River. The other source is very likely from saline lakes in the Andean Cordillera east of the salar. Structural interpretations by Frutos (1972) suggest the presence of numerous east–west lineaments, which are the conduits through which lithium-bearing solutions discharge into the salar.

Figure 5. Surface crust of Salar de Atacama (Chile)

Figure 6. Aerial view of Salar de Uyuni (Bolivia)

Figure 7. Surface of the Salar de Uyuni (Bolivia)

The deltaic sediments of the San Pedro River bind the salt nucleus to the north. The surface of the salar is inaccessible because of extensive polygonal cracking. Preliminary drilling by CORFO (Corporación de Fomento; a Chilean state development agency) over various parts of the basin indicated a minimum thickness of 360 m of halite near the center of the basin, diminishing to about 40 m near the southern margin. Drilling by the Hunt Oil Company indicates that the salt thickness may exceed 1,000 m. Salt cores show that only the near-surface portion of the halite crust has high porosity and permeability. A 10-km-long seismic survey revealed that the highest porosity extends to a depth of 20 to 25 m and that some additional lower-porosity halite may exist at depths from 25 to 35 m. Below this depth, salt cores show complete recrystallization of the halite into a solid mass, devoid of any pores. The yield characteristics of the upper halite layer were determined by drilling and testing shallow wells to 30 m and 60 m. The wells, pumped for 3 months at 64 L/sec, stabilized at drawdowns of 20 cm/sec and 7.9 m, respectively, corroborating that only the upper 30 m have a high transmissivity.

Salar de Uyuni, Bolivia

The Salar de Uyuni is in southwestern Bolivia at an elevation of 3,653 m. The salar represents an immense body of salt, with a maximum

Table 1. Partial cation chemical analyses, wt %

Cation	Silver Peak, Nevada	Salar de Atacama, Chile	Salar de Uyuni, Bolivia
Li	0.023	0.14	0.025
K	0.53	1.87	0.62
Na	4.43	6.92	9.1
Mg	0.033	0.91	0.54
Mg:Li	1.5	6.6	21.5

surface dimension reaching 120 km (Figure 6). The surface of the salar is smooth (Figure 7).

Meager subsurface data suggest that the salt crust is about 15 to 20 m thick. Extensive development of algal reefs some 75 m above the present surface of the salar attests to the existence of a much larger and less saline ancestral body of water—Lake Minchin (quite reminiscent of the ancestral Lake Lahontan and the present Great Salt Lake in Utah). The presence of several algal terraces suggests lowering of the lake level in several stages. The ultimate stage represents saturation with respect to sodium chloride and resulted in the precipitation of present crust. A sample collected from a depth of 15 cm beneath the surface of the salt crust by W.D. Carter (Ericksen, Vine, and Ballou 1978) gave a radiocarbon date of $3,520 \pm 600$ years, suggesting that salt precipitation may have begun some 350,000 years ago. Comprehensive reports on the studies conducted on the Salar at the request of the Bolivian Government have been prepared by Ericksen, Vine, and Ballou (1978) and by the Servicio Geológico de Bolivia (Ballou and Risacher 1981).

All three basins contain abnormal lithium concentrations. As mentioned previously, the lithium must be attributed directly or indirectly to volcanic geothermal activity of Recent or older age. There is no doubt, however, that the strength recorded today in the brine is the direct result of an intense concentration mechanism resulting from natural solar evaporation.

Table 1 shows some partial chemical analyses of the major cations contained in the three brines. All analyses represent the averages of several samples collected in each of the basins and early production averages from the well field for Silver Peak.

The Salar de Atacama contains the highest lithium, potassium, and magnesium concentrations (Table 1). Concentrations up to 7,000 ppm Li have been recorded in the Salar de Atacama brines. Several sources of lithium have been identified, but the most important was from the leaching of the volcanic rocks surrounding the salar. A second source was the weathering and leaching of exposed lacustrine sediments predating the formation of the salar. Geothermal fluids such as those of the El Tatio (28 to 47 ppm Li) represent a third source (Ide and Kunasz 1989). Of the three basins, however, there is no question that the evaporation-concentration mechanism was most intense for the Atacama Basin. Table 1 also indicates that ratios between various cations in the brine are different between the three basins, which strongly argues for different compositional inputs. The chemistry, specifically the Mg:Li ratios, also illustrates one of the important aspects controlling the production of lithium from different brines. In systems with high Mg:Li ratios, the phase chemistry prevents the formation of lithium chloride brine unless the magnesium is removed at the start of the process. This has been achieved in Clayton Valley (Barrett and O'Neill 1970) and at the Salar de Atacama. The exceedingly high Mg:Li ratio has prevented the development of the Salar de Uyuni (and the Great Salt Lake) as an economic source of lithium.

PRODUCTION FROM BRINE DEPOSITS

Historically, lithium chemicals and mineral concentrates were produced from pegmatites. The most important was the Kings Mountain Belt of North Carolina, where the two major producers (Chemtall Foote Corporation and FMC Lithium Division) mined and produced lithium concentrates, mineral concentrate by-products, and lithium chemicals.

In the early 1960s, Foote Mineral Company started developing the Silver Peak, Nevada, brine operation (Barrett and O'Neill 1970). Although the American Potash Corporation produced some lithium as a by-product at Searles Lake, California (1938–1978), Silver Peak was unique because it represented a primary source of lithium carbonate from a brine deposit. Its uniqueness led to the investigation and identification of lithium in numerous other salars around the world and the eventual new production from Chile (Salar de Atacama) and Argentina (Salar del Hombre Muerto).

Clayton Valley, Nevada

Foote Mineral Company traces its origins to A.E. Foote, who founded the company in 1876 as a purveyor of rare minerals. It became a major producer of lithium chemicals when it acquired the right to mine spodumene at Kings Mountain, North Carolina, in the early 1950s. In the 1960s, Foote pioneered the production of lithium carbonate from brine with the opening of the Silver Peak plant (Clayton Valley). It was acquired by Cyprus Minerals Company, then by Chemetall of Germany and more recently by Rockwood Specialties.

The Clayton Valley salt marsh was first investigated during the World War II effort to locate sources of strategic minerals, one of which was potash. The salt marsh area was leased by the American Potash Corp., which let the leases lapse. The leases were picked up by the Leprechaun Mining Company (Clyde Kegel), which conducted some exploration on the subsurface brines and identified lithium in addition to potassium. An agreement was later negotiated with Foote Mineral Company, which developed the brines of the basin as a source of lithium carbonate (Barrett and O'Neill 1970).

In Clayton Valley, lithium-bearing brines occur in an asymmetric, undrained structural depression filled with Quaternary sediments composed mainly of clay minerals, including hectorite, volcanic sands, and alluvial gravels, and saline minerals consisting of gypsum and halite (Kunasz 1970). The brine that saturates the sediments is chemically simple. It is a concentrated sodium chloride solution containing subordinate amounts of potassium and minor amounts of magnesium and calcium. The lithium concentration is variable and decreases with pumping; the lithium concentration in the brine varies from 100 to 300 ppm Li. The dominant source of lithium has been a volcanic ash that extends across the basin. Exploration has identified additional aquifers and they supply additional volumes of lithium-bearing brine.

An extensive well field supplies the brine into some 4,000 acres of solar evaporation ponds (Zampirro 2004). Over 12 to 18 months, concentration of the brine increases to 6,000 ppm Li through solar evaporation. When the lithium chloride reaches optimum concentration, the liquid is pumped to a recovery plant and treated with soda ash, precipitating lithium carbonate, which is then filtrated out, dried, and shipped. Domestic production of lithium carbonate from brine is limited to Chemetall Foote's operation in Nevada. At this time, the Silver Peak operation is one of the world's leading producers of lithium hydroxide. Chemetall Foote also produces normal and secondary butyl-lithium at its New Johnsonville, Tennessee, facility and a number of downstream products (lithium chloride, bromide, and sulfate; U.S. Pharmacopeia- [USP-] grade lithium carbonate and high-purity

Figure 8. Salar de Atacama—lithium, ppm

lithium carbonate; lithium metal ingots and foils for the primary battery industry) at Kings Mountain, North Carolina.

Salar de Atacama, Chile

Two companies produce lithium carbonate and other salts from the brines of the Salar de Atacama: SCL, wholly owned by Chemetall Foote, and SQM.

In the 1990s large-scale production of lithium carbonate shifted from the United States to South America (Chile and Argentina). IIG made the first published reference on the occurrence of lithium in Chile in 1969 when it undertook an extensive survey of the Salar de Atacama. The institute published its findings in 1974 (Moraga et al. 1974). Subsequent studies by CORFO showed that the salt nucleus contains a resource of 4.3 Mt of lithium (Penner 1978). In April 1974, Foote Mineral Company (Cyprus Foote Mineral Company) verified the high lithium concentrations in the shallow brines below the saline crust. In January 1975, an agreement was signed with CORFO to initiate a 4-year feasibility study to assess the potential of producing lithium carbonate from the brine. The results of an exploration program based on test holes drilled on 5-km centers revealed very high lithium concentrations (Figure 8) over most of the salar (1,000–7,000 ppm Li).

SCL, a subsidiary of Chemetall Foote, has been exploiting the brines from the southern portion of the salar since 1984. The saturated brine is found 50 cm below the salt crust in a porous upper salt layer that reaches a thickness of about 30 m. It is pumped via standard wells to a series of extensive, plastic-lined, solar evaporation ponds (Figure 4). The initial phase chemistry is controlled by mixing brines from separate sectors of the salar to

remove the magnesium and sulfate at the early stages of evaporation. The final brine, concentrated to about 6% LiCl, is then transported by rail to the port city of Antofagasta, where it is converted to Li_2CO_3 by reaction with sodium carbonate. The combined SCL production between the Silver Peak, Nevada, and the Salar de Atacama operations is approximately 20,500 tpy. SCL also harvests KCl as a by-product at the salar.

Exploration by a number of companies over the northern portion of the Salar de Atacama led to its development as a second chemical production center. SQM, the Chilean nitrate producer, acquired the development rights and started the production of potassium chloride, potassium sulfate, and lithium carbonate in 1997.

SQM is the world leader in specialty fertilizers, iodine, and lithium carbonate. Created in 1968 as part of a plan to reorganize the Chilean caliche (sodium nitrate) industry, SQM is today the lowest cost producer worldwide of potassium chloride, lithium carbonate, potassium sulfate, and boric acid. Between 1994 and 1998 the company developed the largest nonmetallic project in Chile: the Salar de Atacama project. The three stages of the project required an investment of US\$300 million. The first stage was to build a 300,000-tpy potassium chloride plant, which currently produces about 170,000 tpy KCl. The entire output is consumed internally, supplying raw material to SQM's potassium nitrate production. The second stage was to produce lithium carbonate with a design capacity of 23,000 tpy from brines obtained from the potassium chloride production process. The last stage, begun in 1998, was the construction of a potassium sulfate plant that now also produces boric acid as a by-product. The company also produces boron chemicals. SQM avoided the issue of the high magnesium concentration by mixing brines of different compositions, resulting in a phase chemistry that led to the precipitation and subsequent harvesting of various salts (sylvinite, potassium sulfate, and boric acid). The excess residual brines are reinjected into the salar. Trucks carry the saturated solution of lithium chloride from the Salar de Atacama to the plant at the Salar del Carmen, east of Antofagasta, where it is purified by removing the remaining boron and magnesium through extraction and filtering processes. Finally, the purified lithium brine is reacted with sodium carbonate to produce lithium carbonate, which is filtered, washed, dried, and packed into different kinds of products. The production of lithium carbonate started at 22,000 tpy. SQM now produces 40% of the world's lithium carbonate. The company has also started production of butyl-lithium at its Bayport, Texas, plant and has acquired LithChem, a producer of lithium carbonate and lithium hydroxide.

Salar del Hombre Muerto, Argentina

Several lithium occurrences have been documented in the Argentinian Altiplano (Poppi 1981). Discovered as a result of an Earth Resources Technology Satellite (ERTS) collaborative project (Nicolli et al. 1980), several salares (Hombre Muerto, Rincon, Pastos Grandes, and others) were explored. In 1995, FMC Lithium purchased the rights to the Salar del Hombre Muerto, a salar containing high, uniform concentrations of lithium with low levels of other contaminants. The Salar del Hombre Muerto is in the high Andes at about 4,025 m above sea level, about 1,400 km northwest of Buenos Aires. The location is convenient to major rail lines and seaports. Covering a smaller area than most salars of the region, it contains lithium brines at depths much greater than its neighbors. The site investigation involved core drilling, testing, sampling, and hydrological studies. Reserves were estimated using geostatistical techniques and a three-dimensional flow model with coupled solute transport, which indicate a reserve of 75 years. The concentrations

of lithium in these brine deposits range from 200 to 2,000 ppm and can be further concentrated using solar evaporation. Contributing to efficient solar evaporation and concentration of the brines are the low rainfall and humidity, high winds and elevations, and relatively warm days in the area of the salars. When such conditions are present, highly concentrated brines can be produced at reasonable cost and used as feedstock for a lithium carbonate plant.

While mining spodumene in North Carolina, FMC perfected and commercialized a selective purification process extracting nearly pure lithium chloride from the salar brine with minimal processing (*North American Mineral News* 1995). The Salar del Hombre Muerto area also contains plentiful fresh water needed by the selective purification process. Selective purification uses low-cost raw materials housed in modular units. FMC has installed production facilities for both lithium chloride and lithium carbonate from the Salar del Hombre Muerto. Between 1999 and 2003, FMC produced an average of 4,800 tpy (Ober 2003), well short of the planned production capacity. With its market position in soda ash, FMC planned to produce lithium carbonate at a competitive cost. The company recently announced, however, that it will source its carbonate requirements from Chile under a supply contract with SQM (Ober 2000). FMC also produces downstream lithium products at Bessemer City, North Carolina, and at Bayport, Texas.

Potential Brine-Producing Districts

Argentina—Salar del Rincon and Others

Equity-1 Resources of Australia has been involved in developing Salar del Rincon. In addition to significant lithium, the brine contains high concentrations of sulfates, resulting in a complex phase chemistry that must be resolved before lithium can be economically recovered.

Qinghai Basin, People's Republic of China

As a result of the shift of lithium carbonate production from pegmatite source to brines, the Chinese spent much effort to identify and exploit brine deposits in the Qaidam Basin of northwestern China. A number of playas (salt lakes) have been identified. In the Golmud Area, brines have been exploited for potash and Chinese researchers have undertaken renewed efforts to produce lithium from the salt lakes of Tajinar and Yiliping, where high lithium concentrations have been recorded. The Mg:Li ratio is, however, very high and thus is a key to solving the process flowsheet (Peihua and Pengxi 2000).

The Qaidam Basin is in northwestern China's Qinghai Province. Several playas have been explored, and some could quite possibly become centers of lithium chemical production. A group of scientists from the Qinghai Institute of Salt Lakes of the Chinese Academy of Sciences has successfully solved the problem of separating lithium from the brine solution, which contains a high concentration of magnesium. The province will set up a company capable of producing 100 tpy of lithium chloride, near the Dong Tajinar Lake. The Qaidam Basin has about 33 salt lakes with a reported resource estimated at nearly 14 Mt of lithium chloride. At present, the basin is China's largest production base for potash fertilizer (*People's Daily* 2000).

Tibet

Lake Zabuye is one of 352 salt lakes on the Qinghai-Xizang (Tibetan) Plateau. The lake lies in a closed basin at an elevation of 4,421 m. The evaporation of these alkaline chloride-sulfate waters has led to a complex set of evaporitic minerals. Of importance is the occurrence of zabuyelite, which precipitates from the lake waters as natural lithium carbonate. The source of the rather extraordinary

high levels of lithium (800 ppm) is most likely of geothermal origin, because the springs that feed the lake are abnormally high in lithium (Holland et al. 1991). A recent announcement (*China News* 2005) indicated that 240 million yuan (US\$29 million) have been invested in 2003 to build the Baiyin lithium carbonate plant in Lake Zabuye. The plant capacity is reported to be 5,000 tpy of lithium carbonate.

PRODUCTION FROM PEGMATITE DISTRICTS

Following the shift to lithium carbonate to Chile, the pegmatite-mining district of North Carolina was no longer able to compete economically. The two mining operations closed down, although the sites continue to produce downstream lithium chemicals. Similarly, the two major producers no longer produce spodumene and other mineral concentrates. The slack was picked up by the three dominant producers in Canada (Tanco), Australia (Greenbushes), and Zimbabwe (Bikita).

Australia

Spodumene is mined from a zoned pegmatite in the southwest of Western Australia, approximately 300 km south of Perth and 80 km east of the Port of Bunbury. Sons of Gwalia acquired a 100% interest in the Greenbushes mine in 1998.

The Greenbushes pegmatite is the largest hard-rock tantalum resource and the largest and highest-grade lithium mineral resource in the world. The deposit is a zoned pegmatite with a strike length of more than 3 km. It contains zones of tantalite, spodumene, sodium, and potassium feldspars with some overburden of very white, high-grade kaolin.

Mining in the area has continued almost uninterrupted since tin was first discovered in 1888. The spodumene deposit was identified in 1980 during the extensive drilling program for tantalum. By 1983, initial development of the spodumene ore body commenced and, by 1985, a 30,000-tpy spodumene concentrator was commissioned. This was later increased to 100,000 tpy capacity in 1993–1994 and again to 150,000 tpy capacity in 1996–1997. The ore reserve and resource are >13 Mt, that is, sufficient to supply high-grade products for several decades.

The Minerals Processing Plant, constructed in 1980 as a tantalum pilot plant, was converted to the Lithium Minerals Processing Plant in 1983. The plant was expanded several times, the latest in 1995, to meet increased demand for spodumene. This plant liberates and recovers the spodumene into several spodumene minerals by milling, screening, flotation, gravity, and magnetic separation processes to meet the requirements of the various product applications.

The Greenbushes operation produces about 60,000 tpy of spodumene concentrates. It supplies about 60% of the world market. The highest quality concentrate has a grade of 7.5% Li_2O . The company also produces several other concentrates. A chemical plant was constructed but was mothballed after a fall in the world price of lithium (ACTED 1997).

Canada

Tantalum Mining Corporation of Canada is part of Cabot Specialty Fluids, a division of Cabot Corporation, Boston, Massachusetts. It produces spodumene from a zoned pegmatite and operates a concentrating plant at Bernic Lake, Manitoba, Canada. The site is about 130 km northeast of Winnipeg.

The Bernic Lake pegmatite is one of a number of subhorizontal pegmatite sheets in the Bird River greenstone belt within the Superior geological province in the Canadian Shield. It was formed during the Kenoran Orogeny of the Late Archean age and is approximately 2.5 billion years old. Internally, the pegmatite is

composed of eight discrete mineralogical zones comprising economic minerals containing tantalum, lithium, cesium, and rubidium, each occurring in separate zones. The various minerals are spodumene, montebrasite, wodgonite, microlite, pollucite, lepidolite, and feldspar. Jack McNutt discovered Bernic Lake in 1929, and the area was first exploited for tin (Vanstone et al. 2000). Commercial production began in 1969 with tantalum concentrates as the major mineral. In 1984, Tanco began producing spodumene concentrates, supplying Corning. Pollucite was also sold to the Soviets. Currently, the mine produces tantalum, cesium, and lithium.

Access is through both a decline and a shaft. Mining is carried out using the room-and-pillar method. Processing consists of crushing to –12 mm, with tantalum and lithium ores stored separately, and pollucite and rubidium are collected into direct-sale stockpiles. Tantalum is recovered via gravity separation and the concentrate is sent directly to Cabot's Bozertown, Pennsylvania, plant. Spodumene is sent to a dense medium circuit where feldspar is removed. Further cleaning is achieved through a series of flotation and gravity separations that remove tantalum, phosphates, mica, feldspars, and quartz. Separation produces an additional lithium concentrate, montebrasite, a lithium aluminum phosphate and spodulite, obtained as the coarse fraction from the spodumene reject circuit. The spodulite concentrate contains 5% Li_2O . Magnetic separation removes any extraneous iron. Pollucite is further processed by leaching to produce cesium chemicals (Hilliard 2002).

Zimbabwe

The largest lithium-bearing area in Zimbabwe is the Bikita tin fields, which is about 60 km east of Masvingo. Important mineralized zones are in the Al Hayat, Bikita, and Southern sectors. The pegmatite is about 1,700 m long, and its width varies from 30 to 70 m. It strikes north-northeast and dips from 14° to 45° east. The pegmatite is asymmetrically zoned and contains a variety of commercially important lithium minerals as well as beryl and pollucite. Bikita Minerals (controlled by AMZIM Minerals, a company in the United Kingdom) produces standard petalite, low-alkali petalite, container-glass petalite, and spodumene concentrate.

Other minor lithium-bearing occurrences are in the Wankie, Salisbury, Umtali, Mtoko, Insizi, Matobo, and Mazoe districts (Toombs 1962).

Production of lithium minerals increased from 18,064 t in 1993 to 49,883 t in 1997 (Mobbs 1998) but declined to 33,000 t in 2002 (Cockley 2002).

Other Producing Regions

Russian Federation

The Russian Federation produces spodumene and other mineral concentrates at the Pervomaisky mine, southeast of Chita. The spodumene occurs in unzoned pegmatites that intrude amphibolites, reminiscent of the Kings Mountain system. The narrower veins are not mined selectively, which requires belt sorting to remove the host rock before processing and production of spodumene concentrates and other minerals recovered. The concentrates are hauled more than 2,000 km to processing facilities in Krasnoyarsk, where the spodumene is converted to lithium hydroxide and metal and then further transported to Novosibirsk, where lithium carbonate and other chemicals are produced (production data unavailable). Low-cost carbonate production from Chile shut down the plant.

Historically, the former Soviet Union obtained its spodumene concentrates from the People's Republic of China from a mine in the Altai Mountains (near Fuyun) in Sinkiang Province. When the Soviets realized that they were going to be ousted, they began an intensive development program of the pegmatite field identified

southeast of Chita and built a self-contained infrastructure at Pervomaisky. After the 1959 events, China took control of the Sinkiang region, and the Soviets were left to their own means. Pervomaisky became the source of the spodumene for the Soviet military-industrial complex.

People's Republic of China

The People's Republic of China produces lithium and other mineral concentrates (beryl, lepidolite, high-purity quartz) from a mine in the Altai Mountains in northwestern China. The lithium concentrates are trucked some 600 km to Urumqi, the capital of Sinkiang Province, where a processing plant produced lithium hydroxide using the old Foose Mineral lime–spodumene process. With the recent information on the production of lithium carbonate, it must be assumed that the plant has been partially converted to the acid-roast process. Low-cost lithium carbonate from Chile may have shut the plant down (Ober 2000).

Minor Producing Districts

Argentina

In Argentina, lithium-bearing pegmatites occur in the western part of the Sierras Pampaneas region, which includes the productive districts of San Luis, Córdoba, and Catamarca. The pegmatites are zoned and contain spodumene. The reserves, considered to be small, total about 18 kt as spodumene (Angelleli and Rinaldi 1963, 1965).

Brazil

In Brazil, lithium-bearing pegmatites occur in the Minas Gerais and in the northeastern part of the country, which includes the states of Paraíba, Rio Grande do Norte, and Ceará (Afghouni 1978).

In the state of Minas Gerais, near Aracuai, several pegmatites have been exploited on a sporadic basis. The pegmatites, which carry spodumene, amblygonite, petalite, and lepidolite, have been traditionally mined for cassiterite, tantalite, and beryl, and lithium minerals have been sporadically recovered. As a result of an increase in demand for lithium minerals (petalite), exploration activities resulted in the discovery of important petalite pegmatites, reported to contain 100 kt of petalite grading 2% Li. Spodumene reserves have been estimated at 300 kt, whereas lepidolite reserves are considered to be nearly exhausted.

The most important producer of lithium minerals is Arqueana de Minerios e Metais (Sao Paulo). The company mines spodumene, petalite, lepidolite, amblygonite, beryl, and cassiterite from the pegmatite bodies near Aracuai in Minas Gerais. The company also supplies spodumene concentrates to Companhia Brasileira do Litio (CBL), a small producer of lithium carbonate and lithium hydroxide (Ober 2003). The processing facilities have been constructed in an economically depressed region several hundred kilometers north of the mining district to benefit from government incentives. The plant is estimated to produce about 1,500 t of lithium carbonate (K. Afghouni, personal communication).

Other Areas

Lithium minerals are also produced in Portugal (lepidolite), Spain (lepidolite), and Argentina (spodumene and amblygonite).

NEW PRODUCERS

Toxco

Toxco, a California company, offers any organization within the U.S. federal government a preapproved battery recycling contract.

It is a company certified in the recycling of various lithium battery types as well as other metal types (Toxco 2003).

In 1995, Toxco won a contract for the purchase of 68 million pounds of depleted lithium hydroxide monohydrate, used in the 1950s and 1960s at Oak Ridge, Tennessee, for the production of lithium isotopes for use in the production of thermonuclear weapons (Frank 1995). LithChem International, a subsidiary of Toxco that produces lithium carbonate and lithium hydroxide in Baltimore, Maryland, was purchased by Soquimich, the Chilean fertilizer and lithium producer. Another subsidiary, Ozark Fluorine Specialties, produces hydrofluoric acid, which is converted to lithium hexafluorophosphate, high-purity lithium fluoride, and other electrolytes used in lithium batteries at its Tulsa, Oklahoma, plant.

Potential Producing Districts

People's Republic of China

The Jiajika pegmatite in Sichuan Province was discovered in 1959 and explored in the period 1959–1992. It is the largest lithium mineral deposit in Asia, with reserves, as defined by China, of 1.03 Mt of 1.28% Li₂O. The deposit is easily accessible by existing infrastructure.

The Lushi pegmatite field, in Henan Province, extends more than 100 km², and numerous veins have been discovered.

Sterling Group Ventures of Australia, through a holding subsidiary, has signed two agreements to develop the Jiajika and Lushi deposits. The joint venture is expected to operate the Jiajika deposit with an initial capacity of 240,000 tpy and produce 47,320 tpy of concentrates (6.09% Li₂O).

On April 10, 2004, Sterling entered into a formal joint-venture agreement with Lushi Guanpo Minerals Development (Lushi) of Henan Province of China to bring the project into production and earn 90% of the interest of the project. According to Chinese geological brigades, the property is estimated to contain about 200,000 t Li₂O grading 1%. The concession covers about 100 km² and has large potential to increase the resources of lithium.

Democratic Republic of the Congo

Probably the largest hard-rock lithium resources in the world are in the Manono and Kittolo in the Democratic Republic of the Congo. Currently Congo-Etain mines only cassiterite and columbite from the Manono pegmatite, which is 5 km long and from 120 to 425 m wide. The adjoining Kittolo pegmatite has similar dimensions. Although the pegmatites are apparently zoned (Varlamoff 1954), their dimensions imply spodumene reserves that dwarf the currently known world reserves. The deposit may not have an economic value for years, however, because of very poor transportation facilities. The deposit is about 2,200 km from the Angolan port of Lobito.

Canada

Avalon Ventures was developing the Separation Rapids rare-metals project in northwestern Ontario not far from the Tanco operation. Avalon was increasing the capacity of its flotation pilot plant to be able to produce large enough volumes to provide potential customers with enough high-grade petalite concentrate for sampling.

AMZIM Minerals, the offshore holding company of Bikita Minerals, the Zimbabwe petalite producer, planned to produce petalite at a site owned by Emerald Fields Resource Corp., a Canadian company, from the same pegmatite body between the Tanco and Avalon operations. This operation was named the Big Mack. If all the tests turned out as expected, construction of a plant with an initial production capacity of 15,000 tpy of petalite concentrate was to

begin by the spring of 2001. Resources at the Big Mack are conservatively estimated at 300,000 t, but only a small portion of Emerald Field's 18,200 ha (45,000 acres) has been drilled (*Industrial Minerals* 2000).

Lithium Metal Technologies (Limtech), a subsidiary of Lithos, both Canadian companies, evaluated options for expanding its high-purity lithium carbonate plant to produce more than its current 300 tpy for sale to specialty-glass manufacturers. Limtech purifies technical-grade lithium carbonate from about 99.3% purity to a high-purity 99.999% product that can sell for \$50 to \$70/kg. The company was considering an additional production line with capacity of 1,000 tpy (*North American Mineral News* 2000).

Raymor Industries announced the successful development of a process to produce lithium metal directly from spodumene (*North American Minerals News* 1999). The process was developed and tested at McGill University's Department of Mining and Metallurgical Engineering under contract with Raymor Industries. The company asserted that the new process would have the lowest production costs and highest purity for lithium metal production. The company was granted exclusive rights to the new technology that was to be patented. For feedstock, Raymor Industries intended to use spodumene mined from its La Motte deposit in Quebec and purchased spodumene (Raymor Industries 2000). A drilling project at the La Motte deposit estimated reserves at 4.55 Mt at 1.07% Li₂O from the surface to a depth of 100 m with an additional 2.5 Mt below 100 m.

FUTURE RAW MATERIALS

Several areas of the world carry potential lithium raw materials in the form of brines, geothermal brines, oil-well brines, and clays.

Among the existing brine deposits, the Great Salt Lake of Utah constitutes an important potential source of lithium chemicals. The lake holds brine formed as a result of concentration by solar evaporation of waters contained in the much larger and more dilute Lake Bonneville (Pleistocene). In the Bear River basin, Great Salt Lake Minerals and Chemicals constructed 5.7 km² of ponds and is producing sodium chloride and potassium and sodium sulfates. The recoverable lithium resources are estimated at 286 kt (Evans 1978).

Lithium is also present in several other salares in Chile (e.g., Punta Negra, Pedernales), in the Altiplano of Argentina (e.g., Pastos Grandes, Rincon), in the People's Republic of China (Qinghai Basin), and in Tibet (Lake Zabuye). Lithium has also been reported in underground brines in Israel (Ober 2000).

A potential geothermal area lies within the Imperial Valley of Southern California. The chemically complex brine contains large concentrations of sodium, calcium, and potassium. It also carries about 0.020% Li. Koenig (1970) indicated that the volume on the brine under an area of 31 to 62 km² is >4 km³. This suggests a potential reserve >840 kt Li. Lithium is also present in significant concentrations in the flashed brines of the Cerro Prieto geothermal field in Baja California, Mexico. The potential exploitation of lithium will depend, however, on whether or not some complex chemical engineering problems are solved.

Other geothermal areas include the Reykanes Field of Iceland, where the visible active sector covers about 5 km². Feasibility studies (Ludviksson and Hermannsson 1970) indicate that a yearly production of 500 t of lithium compounds is possible. The brine contains 8 ppm Li. Additional thermal areas are known at Reykir, Hveragardi, and Drysvik (Karlsson 1961; Prast 1972).

A similar potential source of lithium is the geothermal waters at Wairakei, New Zealand. Potential production from bore waters containing 13 ppm Li are estimated at 2,400 tpy as Li₂CO₃, assuming a discharge rate of 3,785,000 L/hr (Kennedy 1964).

Lithium-bearing clays are known to occur in several localities in the United States. The highest lithium value of 0.53% has been recorded at Hector, California, where the Baroid Division of National Lead Co. mines hectorite for its swelling characteristics (Ames, Sand, and Goldich 1958). Hectorite has been identified in Clayton Valley, where it occurs as an alteration product of volcanic ash along a fault zone and is one of the clay minerals in Tertiary and Quaternary lake sediments (Kunasz 1970). The hectorite contains 0.24% to 0.35% Li. At Spring Mountain, Utah, 0.11% Li has been reported in beryllium-bearing tufts (Shawe 1968), where lithium probably also occurs in hectorite. An important discovery of lithium-bearing clays has been made in the McDermitt caldera in northern Nevada. The occurrence of lithium-bearing clays is also reported (Norton 1965) in Yavapai County, Arizona (0.10% Li), in Tertiary clays at Kramer, California (0.19% Li; Muessig 1966), and in the Turlari playa (0.14% Li) in Argentina (Muessig 1966). An extensive survey by the Lithium Exploration Group of the U.S. Geological Survey (USGS) indicated that vast resources of lithium lie in a great number of sedimentary clays (Vine 1976). The U.S. Bureau of Mines conducted extensive research on the extraction of lithium from clay. Extraction of lithium from clays associated with boron deposits at Begadic in Turkey was recently evaluated (A. Buyukburc and G. Koksall, 2005). Although clays contain lithium concentrations on the same order of magnitude as commercial pegmatites, they are not likely to become lithium sources in the near future because of technological problems associated with the extraction of lithium from the crystal lattice, and also because they cannot compete with the low-cost brine operations in the United States and Chile.

RESERVES

In the 1970s, an accelerated research effort in the field of secondary batteries and thermonuclear power generation prompted the National Research Council to create the Lithium Subpanel charged with evaluating available lithium reserves and resources in the world. The resulting study (Table 2) concluded that the reserves and resources of all classes of lithium occurrences were 10.6 Mt (Evans 1978). At that time the brines of the Salar de Atacama were estimated to contain 4.3 Mt of lithium. Today these reserves are the most significant because they supply the two operations, which produce a substantial amount of the world's lithium carbonate.

According to estimates published by the USGS, Chile holds approximately 73% of the world's lithium resources; followed by China, 13%; Canada, 4.5%; and Australia, with just over 4%. Resource data are not available for some important producing countries, including Argentina, China, and Russia. Lithium resources occur in two distinct categories: lithium minerals and lithium-rich brines. Lithium brine resources, now the dominant feedstock for lithium carbonate production, are produced mainly by Chile. Canada and Australia have the most significant hard-rock lithium resources (Ober 2003).

WORLD MARKETS FOR LITHIUM

The world lithium production has grown from 6,300 t Li equivalent in 1994 to 11,900 t Li equivalent in 2000. Chile, because of the expansion in brine production by SQM in 1996 became the world leader of lithium carbonate (Roskill Information Services 2004).

In descending order of production, the world's largest lithium chemical producers in 1999 were Chile, China, the United States, Russia, and Argentina. Australia, Canada, and Zimbabwe were major producers of lithium ore concentrates.

The United States remains the leading consumer of lithium minerals and compounds. It also led production of value-added

Table 2. World lithium resources

Class	Lithium, t*

§ na = not available.

lithium materials. Because only two companies produced lithium compounds for domestic consumption and for export to other countries, reported production and value of production data could not be published by USGS.

In 1999, the only active lithium carbonate plant in the United States was at a brine operation in Nevada. Two other mines in North Carolina closed in 1986 and 1998. Subsurface brines have become the primary raw material for lithium carbonate because of lower production costs compared to hard-rock ores. Ore concentrates rather than lithium carbonate and compound feedstock accounted for the majority of mined lithium minerals consumption.

U.S. imports of lithium carbonate from 1999 through 2002 included Chile, 90%; Argentina, 9%; and others, 1%. In 2003, the respective percentages were Chile, 73%, and Argentina, 27% (Ober 2003).

USES

Lithium is marketed in numerous applications. It is used in three basic forms: ore and concentrate, metal, and manufactured chemical compounds.

Ores and concentrates are consumed by the glass, ceramic, and porcelain enamel industries. Petalite, lepidolite, and amblygonite can be used without prior beneficiation, except hand-cobbing, whereas spodumene must be beneficiated by grinding and flotation,

leaching, and magnetic separation. Lithium is useful because it creates favorable internal nucleation conditions. By comparison, sodium favors external crystallization. Because of its small ionic radius and high field strength, lithium imparts high mechanical strength and thermal shock resistance, as well as good chemical resistance (Fishwick 1966). In these applications, lithium is also introduced in the form of lithium carbonate.

In metal form, lithium is the lightest solid element, having an atomic weight of 6.94 and a specific gravity of 0.534 (at 20°C). Lithium metal is used in the synthesis of butyl lithium. In nonferrous metallurgy, the high reactivity of lithium with gases is used for scavenging oxygen and sulfur, converting them into stable compounds. Lithium is also used in lithium aluminum and lithium magnesium alloys, where it imparts high-temperature strength, improves elasticity, and increases the tensile strength. Demand for aluminum lithium alloys in commercial and military aircraft industries, although encouraging, has not met earlier growth forecasts (Alexander 1992).

Lithium carbonate, in addition to its consumption by the ceramic industry, is being used at an increasing rate in the aluminum reduction cells, where it improves the conductivity of the molten bath, reduces operating temperature, and results in higher production. It is also very effective in reducing fluorine emissions by retaining the fluorine as lithium fluoride in the bath. Lithium carbonate consumption has fallen steadily since its peak in the late 1970s, and, although the rate of decline has slowed in recent years, consumption in the aluminum sector is still forecast to decrease further in the next few years (Roskill Information Services 2004).

In purified form, lithium carbonate is being used in the chemotherapeutic treatment of bipolar disorder (Caldwell et al. 1971).

In the United States, Japan, and Europe, development programs have been initiated on molten carbonate fuel cells. Because of the energy efficiency and environmental cleanliness of all types of fuel cells, worldwide financial support for the development of this technology has increased. Molten carbonate fuel cells are expected to use various lithium compounds, principally lithium aluminates and lithium carbonate (Alexander 1992). Lithium carbonate rather than lithium metal has been the focus of recent research for use in batteries for electric vehicles.

In addition to being the lightest metal, lithium is also the most electronegative metal and, therefore, is ideal for use in many battery applications. Lithium battery characteristics include high energy density, high operating voltage, wide operating temperature range, and long shelf life (Grady 1980). Present applications include heart pacemakers, military hardware, cameras, computer memory backup, watches, and measuring equipment in the oil-drilling industry. Future growth in this area may include use in rechargeable lithium batteries for handheld power tools and electronic and communications equipment and even as a power supply for electric vehicles and the total artificial heart. In fact, double-digit growth is forecast for demand for lithium in secondary batteries to 2006–2007 (Roskill Information Services 2004). The highest value application for lithium batteries remains secondary portable consumer products, especially portable computers and cellular phones. This U.S. market was \$500 million in 1997 and should top \$860 million in 2005. Rechargeable, portable, consumer lithium batteries are expected to grow to a \$3.2 billion market in 10 years.

Lithium hydroxide was first employed as an ingredient in alkaline storage batteries where its presence increased the life of the cells (Bach et al. 1981). In the 1940s, Clarence Earl, who developed special grease by reacting lithium hydroxide with fatty acids, discovered a new application. The resulting grease was found to retain its viscosity over a wide temperature range and remain stable in the

presence of water. Lithium-based greases have become a standard product in military, industrial, and automotive lubrication fields.

Anhydrous lithium hydroxide can absorb large quantities of carbon dioxide, a property that has been used in the air regeneration system of the Apollo command and lunar modules, and in new applications in the mining industry for rescue breathing apparatus.

Lithium chloride and lithium bromide brines have low vapor pressures and are used in absorption refrigeration systems. Lithium chloride also constitutes the feed material for the production of lithium metal. Lithium fluoride is used mainly as a flux in enamels, glasses, and glazes, and in welding and brazing.

The most important organic compound is butyl lithium. It serves as a catalyst in the polymerization of butadiene, isoprene, and styrene to produce polymers with special properties. Butyl lithium has applications in the synthesis of pharmaceutical and agricultural intermediates.

Numerous miscellaneous applications of lithium chemicals include sanitation and bleaching, hydrogen generation, oxygen generation, catalysis, and vitamin synthesis.

PRICES

The prices (*Industrial Minerals* 2004) of various lithium ores (in dollars per short ton) are

Ceramic spodumene:	7.25% Li ₂ O	\$330 to \$350 (free on board [f.o.b.] West Virginia)
Glass-grade spodumene:	5% Li ₂ O	\$195 to \$200 (f.o.b. Amsterdam)
Petalite:	4.2% Li ₂ O	\$165 to \$260 (f.o.b. Durban)

The most dramatic change in pricing occurred in lithium carbonate as result of the new production at the Salar de Atacama, Chile. Lithium carbonate commanded prices of nearly \$ 2/lb into 1997; the large production capacity brought on line by SQM led to a nearly 50% decrease in the world price of lithium carbonate. SQM offered lithium carbonate at 90 cents/lb, forcing the two other major producers to follow suit (Ober 2002). World oversupply has kept lithium carbonate prices depressed for the past 3 years (Ober 2003).

Magnesium Minerals and Compounds

Deborah A. Kramer

INTRODUCTION

Magnesium is the eighth most abundant element and constitutes about 2% of the earth's crust. It is the third most plentiful element dissolved in sea water, with a concentration averaging 0.13%. Although magnesium is found in more than 60 minerals, only a few are of commercial importance. In addition to minerals, seawater and well and lake brines are also important sources of magnesium. One of the more important magnesium minerals is magnesite (MgCO_3), with a theoretical maximum magnesia (MgO) content of 47.6%; this carbonate form represents the world's largest source of magnesia. Other commercially important magnesium-bearing minerals are dolomite, which serves the aggregate industry as well as the chemical industry; brucite, which is used in the production of both caustic-calcined and dead-burned magnesia; olivine, which serves the refractory and heat storage industries; talc, which serves several industries as a filler and as an ingredient in cosmetics; and serpentine. Olivine and talc are discussed in separate chapters of this book. Table 1 shows the composition of these magnesium-containing minerals.

These minerals are the starting raw materials for a wide range of products. These include magnesium metal and several grades of magnesia used for the production of both dead-burned magnesia for refractory manufacture and lighter fired caustic-calcined magnesia. The latter is used in a variety of agricultural, construction, environmental, and industrial applications.

The word *magnesite* literally refers only to the natural mineral, but common usage applies this name to two other types of materials, dead-burned magnesite and caustic-calcined magnesite. For the most part, these are commercial products of magnesia, differing mainly in density and crystal development that results from different levels of heat application. When magnesia produced from seawater or brines first made its appearance on the world market, the products also were called dead-burned or caustic-calcined magnesite, but more recently the technical literature has increasingly referred to the materials as refractory magnesia or refractory-grade magnesia and caustic-calcined magnesia, respectively. These terms are now also increasingly being applied to magnesia products derived from the natural mineral magnesite, especially for those materials with high MgO content. The older terms, however, persist in the trade.

The terms *dead-burned magnesite* or *refractory magnesia* refer to the granular product produced by firing magnesite, magnesium

hydroxide, or another material reducible to magnesia at temperatures exceeding $1,450^\circ\text{C}$. The heat treatment must be of sufficient duration to produce a dense, reasonably weather-stable granule for use in manufacturing refractory materials.

The use of the terms describing magnesia products is somewhat confusing to those not closely connected with the industry. The vagueness of the terminology can lead to misreading of statistics to such a degree that simultaneous shortage and surplus of certain magnesia products is indicated. Confusion has been further amplified by use of such terms as high-purity or super high-purity magnesia; in most cases these terms have been used for magnesia supplied to the refractory industry. They usually refer to the content and relationship of the accessory oxides and density of the material as they affect the refractoriness of the final product rather than any specific MgO content (Duncan and McCracken 1994).

The terms *high grade* and *high purity* generally refer to a refractory magnesia containing more than 96% MgO , a density greater than 3.30 g/cm^3 , preferably 3.40 g/cm^3 , and a proper relationship of auxiliary oxides.

Caustic-calcined magnesia results from 800°C to $1,000^\circ\text{C}$ heat being applied, frequently in a rotary kiln, to magnesite or other material reducible by heat to magnesia. It is heated until less than 10% ignition loss remains and the product displays adsorptive capacity or activity. Caustic-calcined magnesia readily absorbs

Table 1. Chemical composition of selected magnesium-containing minerals

Common Name	Chemical Composition
Brucite	$\text{Mg}(\text{OH})_2$
Carnallite	$\text{KMgCl}_3 \cdot 6\text{H}_2\text{O}$
Dolomite	$\text{CaMg}(\text{CO}_3)_2$
Epsomite	$\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$
Kainite	$\text{MgSO}_4 \cdot \text{KCl} \cdot 3\text{H}_2\text{O}$
Kieserite	$\text{MgSO}_4 \cdot \text{H}_2\text{O}$
Magnesite	MgCO_3
Olivine	$(\text{MgFe})_2\text{SiO}_2$
Schoenite	$\text{MgSO}_4 \cdot \text{K}_2\text{SO}_4 \cdot 6\text{H}_2\text{O}$
Serpentine	$\text{Mg}_3(\text{OH})_4\text{Si}_2\text{O}_5$

water vapor or carbon dioxide (CO_2), an action that is referred to as activity. This activity feature then facilitates the production of high-density periclase. This is generally done through briquetting and the application of additional high-temperature heat. The production of caustic magnesia involves less energy than is required to produce dead-burned magnesite.

Fused magnesia is produced by heating high-grade magnesite to a molten state for up to 6 hours in electric arc furnaces to approximately $3,000^\circ\text{C}$. The resulting product, at 96% to 98% MgO , has a high density of 3.50 g/cm^3 and relatively high chemical stability, strength, and resistance to abrasion. World production is approximately 160 ktpy, which is used in refractories and in electrical products.

PRODUCTION, TRADE, RESERVES, AND RESOURCES

The largest magnesite production facilities in the world are in China, North Korea, and Russia. Together, these three countries account for about two thirds of world magnesite production capacity. Japan and the United States account for one half of the world's magnesia production capacity from seawater or brines. Fused magnesia is produced in Australia, Brazil, Canada, China, Israel, Japan, the Republic of Korea, Mexico, Russia, the United Kingdom, and the United States.

United States

Production and Trade

Figures 1 and 2 give a historical perspective of the supply and demand of dead-burned and caustic-calcined magnesia in the United States. Historically, overall U.S. consumption of magnesium compounds has declined, mainly because of a decrease in demand from the refractories industry, the largest consumer of magnesium compounds. U.S. production actually decreased faster than the drop in consumption because imports of low-cost, dead-burned magnesia from China replaced part of the U.S. production. This can be seen in the significant increase in import reliance that occurred beginning in the 1980s. With the recovery in the U.S. economy in the late 1990s, overall consumption of magnesia increased as steel production increased, but this trend was short-lived. The quantity of refractory magnesia consumed per ton of steel produced continued to decline. For example, in the mid-1970s, the electric arc furnace used about 20 kg of refractories per metric ton of steel produced; this quantity has declined to about 4 kg/t (Pearson 2000).

The United States has one producer of dead-burned magnesia—Martin Marietta Magnesia Specialties LLC (Manistee, Michigan). In 2002, the United States produced 123 kt of dead-burned magnesia. Imports totaled 394 kt, of which 73% was from China, and exports were 73 kt, 75% of which was shipped to Canada.

Caustic-calcined and specialty magnesias were produced by Premier Chemicals LLC (Port St. Joe, Florida) from magnesite in Nevada and from seawater in Florida, and by Martin Marietta and Rohm & Haas Co. (both in Manistee, Michigan) from underground brines in Michigan. U.S. production of caustic-calcined magnesia in 2002 was 127 kt; this was the first year that caustic-calcined magnesia production was greater than dead-burned magnesia production. Imports of caustic-calcined and specialty magnesias totaled 166 kt; China (56%) and Canada (31%) were the primary import sources. Exports were 37 kt, distributed among several countries.

Magnesium hydroxide [$\text{Mg}(\text{OH})_2$] is found as the naturally occurring mineral brucite. In addition, it is produced synthetically from seawater or brines. Small quantities of brucite are recovered in

the United States by one firm, Premier Chemicals, as a by-product of magnesite mining in Gabbs, Nevada. Applied Chemical Magnesias Corp. (Fort Collins, Colorado) recovers brucite from a deposit in Bullhead City, Arizona. The deposit is estimated to contain 450 kt of ore grading 90% brucite (Anon. 1998). The company processes this ore and other materials at a 30-ktpy mill in Arizona into products for use in flame retardants, in animal feed, and for acid neutralization.

Several companies in the United States produce magnesium hydroxide synthetically. SPI Pharma Inc. (Lewes, Delaware) and Premier Chemicals recover magnesium hydroxide from seawater. Martin Marietta Magnesia Specialties and Rohm and Haas recover magnesium hydroxide from underground brines. In addition to its Michigan plant, Martin Marietta operates a 30-ktpy plant near Pittsburgh, Pennsylvania, that produces magnesium hydroxide from imported magnesite. Until September 2003, Dow Chemical Co. (Midland, Michigan) produced magnesium hydroxide from underground brines in Manistee. In addition to selling the magnesium hydroxide for water treatment applications, a magnesium hydroxide slurry was supplied to ANH Refractories Inc.'s (Ludington, Michigan) nearby plant for conversion to dead-burned magnesia; this plant closed in September 2003, leaving the United States with one producer of dead-burned magnesia—Martin Marietta Magnesia Specialties. U.S. magnesium hydroxide production in 2002 was 218 kt; this includes some magnesium hydroxide that was used to make dead-burned magnesia. Imports of magnesium hydroxide were only 4 kt, and exports were 14 kt.

In the United States, magnesium chloride is produced and used in two forms—magnesium chloride brines, which are about 30% magnesium chloride in concentration, and magnesium chloride hexahydrate ($\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$). Great Salt Lake Minerals Inc. (Ogden, Utah) produces both the brines and the hexahydrate. Reilly Industries Inc. (Wendover, Utah) and Western Salt Inc. (Chula Vista, California) produce magnesium chloride brines. Great Salt Lake Minerals and Reilly Industries recover magnesium chloride from brines of the Great Salt Lake, and Western Salt produces magnesium chloride brines from seawater as a by-product of salt production. Magnesium chloride is recovered from either brines or seawater by solar evaporation and sequential precipitation of the dissolved salts. Because there are only two producers, U.S. magnesium chloride production data are withheld by the U.S. Geological Survey. Imports of magnesium chloride in 2002 were 20 kt—90% from Israel—and exports were 5 kt.

Magnesium sulfate can be found as a naturally occurring mineral or it can be produced synthetically. The two most commonly occurring magnesium sulfate minerals are epsomite ($\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$) and kieserite ($\text{MgSO}_4 \cdot \text{H}_2\text{O}$). Although these minerals occur in the western United States, they are not mined.

The three U.S. producers of magnesium sulfate are PQ Corp., Giles Chemical Corp., and Southern Ionics Inc. PQ operates a facility in Utica, Illinois, where it produces a magnesium sulfate solution (25% solids) and $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$ crystal. Giles has two plants that produce magnesium sulfate solutions and magnesium sulfate crystal—in Greendale, Indiana, and Rouses Point, New York. Southern Ionics operates two plants producing 18% to 25% magnesium sulfate solutions in Chickasaw, Alabama, and Baton Rouge, Louisiana.

In 2002, magnesium sulfate production in all forms was 38 kt. Imports of natural kieserite were 13 kt, and imports of synthetic magnesium sulfate were 31 kt. Most of these sulfates were from Germany. Exports of magnesium sulfate in all forms were 18 kt, mainly to Canada.

Figure 2. U.S. caustic-calcined magnesia supply and demand, 1970–2002

Reserves and Resources

The reported estimate of 65 Mt of magnesite (15 Mt magnesium) reserve base in the United States is divided as follows: in Nevada, 88%, including 27 Mt of magnesite containing less than 5% calcium oxide (CaO); in Washington, 11%; and in California, the remaining 1%. Magnesite also occurs in Idaho, Maryland, Massachusetts, New Jersey, New Mexico, New York, Pennsylvania, Texas, and Utah, but reserves have not been estimated in these states (Davis 1957).

Brucite reserves are estimated to total 3 Mt in Nevada, associated with the Gabbs magnesite deposit. Walper (1964) reported brucite reserves of more than 2 Mt in the Marble Canyon area,

Culberson County, Texas. This deposit is being mined by Applied Chemical Magnesias.

Reserves of magnesium salts obtained as brines from underground evaporite deposits are difficult to estimate. Available information on magnesium salts in surface evaporites is insufficient to estimate reserves. The Great Salt Lake contains an estimated 630 Mt of magnesium chloride.

World

Total production of magnesite in 2002 was estimated to be 11.2 Mt, with China, Turkey, North Korea, and Russia as the largest producers, together accounting for about two thirds of total world

Figure 3. World magnesite production by region

production. Figure 3 shows the regional changes in world production since 1970. In 1970, Europe was the largest magnesite-producing area, accounting for 43% of the total. After 1970, however, production in Europe began to decline, and Asia became the leading producing region. By 2000, Asia represented 65% of the total world production of magnesite. China became the leading producing country and accounted for nearly one third of world production. Some of this reported increase in production in China might result from additional knowledge of production facilities that has been developed in the past 10 years and may not represent as large of an increase as it appears. Specific details of individual producers throughout the world are detailed in the next section.

World reserves and reserve base estimates for magnesite are shown in Table 2. The largest reserves occur in the countries with the largest production—China, North Korea, and Russia. Reserves of evaporite minerals and brines are virtually unlimited. The existing quantities of evaporites and brines provide theoretical resources that are much larger than the quantities that are likely to ever be used.

GEOLOGY

Magnesite, when pure, contains 47.8% MgO and 52.2% CO₂. The pure mineral is found occasionally as transparent crystals resembling calcite. Impurities in magnesite ore are mainly varying quantities of the carbonates, oxides, and silicates of iron, calcium, manganese, and aluminum.

Magnesite dissociates on heating to form magnesia and carbon dioxide. When heated sufficiently, the magnesia develops a crystal structure identified with that of the natural mineral periclase. Periclase occurs only rarely in nature and not in a commercially workable deposit.

Although the genesis of natural magnesite deposits can be complex, it is distinguished in nature in two distinct physical forms, namely crystalline, with a wide range of visible crystal sizes, and cryptocrystalline, sometimes referred to as amorphous, where crystals are not detectable to the eye and range from 1 to 10 μm . The two types not only differ in crystal size but in the sizes of the deposits and in modes of formation.

The crystalline form of magnesite has a Mohs hardness of 3.5 to 4.0. The color ranges from white to black with shades of yellow, blue, red, or gray. The color is not a significant indicator of purity, but in a given deposit, an experienced person can often roughly

Table 2. Magnesite reserves and reserve base (Mt of magnesite)

Location	Reserves	Reserve Base
Australia	366	423
Austria	50	75
Brazil	160	630
Canada	100	140
China	1,310	3,000
Greece	100	120

Slovakia	150	1,100
Spain	35	100
Turkey	225	550
United States	35	65
Other countries	1,250	1,400
Total (rounded)	7,500	13,300

grade magnesite ore by observing color and crystallinity. Macrocrystalline deposits occur in relatively few, but generally large, deposits on the order of several million tons. The ore shows marble-like crystalline texture and has sedimentary or metasomatic origin. The specific gravity of cryptocrystalline magnesite ranges between 2.90 and 3.00 g/cm³, whereas the value of pure crystalline magnesite is 3.02 g/cm³. In actuality, the specific gravity of magnesite is typically higher than 3.02 g/cm³ because of the presence of iron carbonate.

The cryptocrystalline variety of magnesite typically occurs in many small deposits, although there are exceptions. Cryptocrystalline magnesite is typically massive with no cleavage and is sometimes descriptively called “bone” magnesite. The fracture is usually conchoidal, with a hardness of 3.5 to 5.0. The color is mainly white, but it can have tints of yellow, orange, or buff. Accessory siliceous minerals such as serpentine, quartz, or chalcedony are generally present. Calcium minerals are normally absent or in low concentration; this contrasts with macrocrystalline ore in which calcite and dolomite are the main impurities.

Magnesite occurs mainly in four types of deposits—as crystalline masses replacing dolomite, as impure crystalline masses replacing ultramafic rocks, as cryptocrystalline masses in ultramafic rocks, and as sedimentary beds and lenses.

Crystalline magnesite deposits in dolomite range in size from pockets containing a few tens of thousands of tons to irregular or lenticular bodies containing greater than 100 Mt. Impurities may range from 2% to 20%. In determining the value of this type of deposit, grade is as critical as size, particularly for the magnesite that will be used to manufacture high-purity refractories.

Deposits of cryptocrystalline magnesite are generally smaller than crystalline magnesite deposits. They occur as nodules, veins, and stockworks in serpentinized zones of ultramafic rocks and also can be found as small deposits in tuffs. Magnesite mixed with talc and with or without quartz occurs as lenses replacing dunite or serpentinized dunite. Deposits of this type are as variable in size as those that occur in dolomite.

Sedimentary magnesite is a brown to gray carbonate rock that probably formed by evaporation. Individual beds can cover tens of acres and can range from several centimeters to several meters in thickness. This type of magnesite is interbedded with dolomite, clastic rocks, or strata of volcanic origin. Even though some sedimentary deposits contain high grades of magnesite, the thin beds cannot be mined economically.

Most carbon dioxide that was needed to form magnesite deposits was probably derived from deep-seated igneous sources, although some may have been supplied through thermal dissociation of underlying carbonate rocks. A very small quantity may have been carried by groundwater. Ultramafic rocks supplied the magnesia that is found in their contained magnesite deposits. The source of magnesium in crystalline deposits in dolomite is less certain. One hypothesis suggests that the magnesia was produced during thermal dissociation of underlying dolomite. A second theory suggests that crystalline magnesite deposits are metamorphosed, recrystallized lenses of sedimentary magnesite; however, this hypothesis does not explain the replacement nature of many, if not most, crystalline deposits (Bodenlos and Thayer 1973).

Brucite has been exploited in the past for the production of magnesia but is no longer an important source because minable concentrations of brucite are rarely found. Theoretically, brucite contains 69.1% MgO and 20.9% H₂O. The mineral is often associated with limestone as well as magnesite, is translucent, and is relatively soft and lightweight. Its hardness is 2.5 and specific gravity about 2.4. The color may be white, but blue or green with a gray cast is a more common coloration.

The brine deposits from which magnesium is recovered are brines derived from sea water, wells, and inland salt lakes. The geologic processes that result in these brines are not well understood because they come from different geologic settings. Some of these brines are pore waters in oil fields, some are deep-well brines from marine salines or peripheral rocks, some are from thermal springs or wells, and some are surface or subsurface brines that were associated with Quaternary salt lakes or seas (Smith et al. 1973).

U.S. MAGNESIA DEPOSITS AND RESOURCES

Magnesite

In the United States, the only large deposits of crystalline magnesite are in Gabbs, Nevada, and Stevens County, Washington (Vitaliano and Callaghan 1956; Bennett 1943; Campbell and Loofbourow 1936; Schilling 1968). The only known deposits of crystalline magnesite replacing ultramafic rock are in north-central Vermont. These deposits consist of gray to faintly greenish-gray

rock in which the magnesite occurs as grains or clusters of grains that range from 0.01 to 30.0 mm in a matrix of fine-grained talc (Bodenlos and Thayer 1973). The largest group of cryptocrystalline magnesite deposits occurs at Red Mountain, California; these deposits originally contained about 1 Mt of magnesite. Additional deposits occur in ultramafic rocks in California, with smaller occurrences in Oregon and Pennsylvania (Bodenlos 1950; Davis 1957). Sedimentary magnesite deposits are limited to a few states in the southwest (Rubey and Callaghan 1936; Vitaliano 1950, 1951). Sedimentary magnesite in California and Nevada is thought to have formed in closed basins (Rubey and Callaghan 1936) and therefore is of evaporite origin.

Brucite

Deposits of brucite are associated with the magnesite deposits in Gabbs, Nevada. The mineral occurs as lenses of massive white to light-brown material that is soft enough to scratch with a fingernail. Impurities include veinlets and grains of magnesite, dolomite, talc, forsterite, and periclase. Because the brucite deposition postdated magnesite deposition, it is likely that the associated intrusions of granodiorite drove off the carbon dioxide in magnesite and formed magnesium hydroxide (Schilling 1968).

In addition to the brucite in Nevada, there is a brucitic marble deposit in the Marble Canyon area in Culberson County, Texas, reportedly containing more than 2 Mt with an average brucite content of 38%. Samples of this ore have shown brucite proportions ranging from 23% to 100%.

Brucite was also associated with magnesite in the Stevens County, Washington, deposit. A lens of translucent gray-green brucite about 6 m by 45 m was mined for a short time (from the 1880s until 1905) and manufactured into ornamental objects. These objects, however, tended to develop a white powdery coating of hydromagnesite, and this was most likely one reason that led to the closing of quarrying operations at the deposit (Campbell and Loofbourow 1936).

Brines and Evaporates

Underground brines in Michigan are a source of much of the magnesium compounds produced in the United States. Magnesium-rich brines are found in the Michigan Basin, a structural basin formed of sedimentary rocks of Paleozoic and Jurassic ages. Interstitial natural brines with soluble salts of magnesium, bromine, calcium, potassium, and sodium are confined within the Detroit River Group substrata. The rocks of this group are mainly sandstones and carbonates, often with anhydrite and/or salt lenses. The group is found below lower Michigan, with outcrops or subcrops at the extreme ends of Michigan's lower peninsula (Landes 1951). In the Ludington area, the principal producing aquifer is about 30 m thick and lies about 650 m below the surface. In Manistee, the thickness of the aquifer is estimated to be the same, but it is about 850 m below the surface.

MAJOR DEPOSITS AND RESOURCES OUTSIDE THE UNITED STATES

Australia

Australia has cryptocrystalline magnesite deposits in Queensland, New South Wales (at Fifield, and Young), and in western Australia at Ravensthorpe. In the Kunwarara deposit, 60 km northwest of Rockhampton, Queensland, low iron nodules of cryptocrystalline magnesite cover an area of approximately 63 km² that is entirely overlain by black clay up to 12 m thick. The deposit is thought to have formed by lacustrine deposition of magnesium bicarbonate derived from the

alteration of serpentinite rock. Evaporation caused hydrated magnesium carbonate to precipitate. Deposition of mud over the magnesite caused further evaporation and the formation of hard nodules of dehydrated magnesite (Minerals Council of Australia 2003). Reserves are reported to be in excess of 122.3 Mt containing 34.8 Mt of magnesite, with approximately one half as low iron reserves (Australian Magnesium Corporation 2000). Australian Magnesium Corporation mines this deposit to produce 180 ktpy of dead-burned and caustic-calcined magnesite and 25 ktpy of fused magnesite.

At Thud dungra, northwest of Young in New South Wales, magnesite occurs as veins and nodules formed by the alteration of mafic rocks by magnesium-rich fluids. The magnesite ore contains 95%–99% MgCO_3 and varies in thickness from 2 to 10 m (Minerals Council of Australia 2003). The Thuddungra mine has been in operation since 1935. Ausmag International (Young, New South Wales) produces about 18 ktpy of caustic-calcined magnesite from magnesite from this deposit.

At a now inactive magnesite mine near Fifield, about 30 km northwest of Condobolin, the ore consists of nodules of massive magnesite that occurs as pockets or veins in decomposed ultramafic rock. In western Australia, hard magnesite nodules in dark clayey material crop out 30 km east of Ravensthorpe. Magnesite also occurs in the Kalgoorlie region (Minerals Council of Australia 2003).

Austria

Austria, one of the oldest magnesite producers in western Europe, has a narrow belt of breunnerite magnesite ($[\text{Mg,Fe}]\text{CO}_3$) extending westward from Semmering. The most important deposits are located at Breitenau, Dietin, Radentheim, Semmering, Trieben, and Veitsch. RHI AG (Vienna) operates two dead-burned magnesite plants at Breitenau and Hochfilzen that have a combined capacity of 300 ktpy. About 800 ktpy of magnesite are mined from the company's deposits as feed material (Kendall 1996).

Brazil

Brazil has substantial reserves of crystalline magnesite. The two major areas are located in the Iguatu area of Ceara Province and in the Eguas range near the town of Brumado in southwestern Bahia. Resources are reported to be in excess of 500 Mt (Bodenlos 1954). Magnesita SA (Contagem, Brazil) is the largest producer of dead-burned magnesite in Brazil, with an annual production of approximately 3 Mt of crude magnesite, 285 kt of dead-burned magnesite, 67 kt of caustic-calcined magnesite, and 12 kt of fused magnesite. It produces three chemically similar grades, M-10, M-20, and M-30B, with MgO contents of 94%, 95%, and 98%, respectively, depending on the degree of sinter. The company increased capacity by 65 ktpy in 2004 with the installation of a new kiln for the production of M-30B grade material (O'Driscoll 2003a).

Canada

There are several magnesite deposits in British Columbia (Grant 1987), but the only one being commercially operated is the Mount Brissolof deposit. This open-pit mine is operated by Baymag (Calgary, Alberta) with a capacity to produce 150 ktpy of caustic-calcined magnesite in two rotary kilns and 14 ktpy of fused magnesite in two electric arc furnaces. Minimum grade of the magnesite is maintained at 96.5% MgO . Because the markets to which Baymag sells do not give a premium for product exceeding this grade, the company mines the ore selectively and blends the varying grades to extend the ore life. Other deposits in British Columbia are beds of crystalline magnesite interlayered with sedimentary rocks in the Kootenays region,

the cryptocrystalline magnesite in the Clinton and Bridge River areas of central British Columbia, and the vein deposits in the fault zones along the Yalakom River and the Pinchi Mountains.

China

The explored magnesite resources in China comprise about 30 Gt in 28 mining areas (Bo and Yuilan 1998). About 85% of these resources are concentrated in the eastern Liaoning Province. The majority of Chinese magnesite ores are macrocrystalline, with a crystal grain size from 5 to 50 mm. In the Haicheng area of Liaoning, the magnesite deposits occur as conformable in intermediate strata between 40 and 500 m thick in host rocks of dolomite and schist; the color of the ore ranges from pink to gray. The main accompanying minerals are dolomite, talc, chlorite, graphite, and pyrite, of which dolomite and talc are the most common. There are also cryptocrystalline magnesite deposits in Inner Mongolia, where the main accessory mineral is opal (Schmid 1984; Bo and Yuilan 1998).

Magnesite mining in Liaoning began in 1913, and China has become the largest producer of magnesite in the world. There are six or seven major producers of dead-burned magnesite in Liaoning, with a total production capacity of 3.5 Mtpy. The Chinese market for dead-burned magnesite, mainly for its steel industry, was estimated to be about 1.5 Mtpy; the remainder is exported primarily to the United States and Europe. China also has about 100 ktpy of capacity to produce caustic-calcined magnesite.

Greece

Greece has deposits of cryptocrystalline magnesite. A deposit located at Vavdos in Khalkidiki region in the southwest Thessalonika was first worked in 1957 and operated until 1987. Other deposits, which have been mined commercially, are located on the island of Euboea and in Ormylia in Khalkidiki. The Euboea operations, which once produced 300 ktpy, have been closed.

The Greek deposits are low in iron and boron and produce a grade of sinter suitable for refractories used in basic oxygen furnaces (BOFs). The magnesite is of high quality but tends to be mixed with some siliceous gangue; beneficiation of all ore is necessary for the production of commercial sinter. Most of the magnesite occurs as veins or small lenses, resulting in high mining costs. The removal of about 80 t of waste and overburden is required to obtain 1 t of magnesite (Hatjilazaridou, Chalkiopolou, and Grossou-Valta 1998).

Grecian Magnesite SA (Athens) operates mines and plants at Gerakini and Kalives, Khalkidiki: three rotary and three shaft kilns at Gerakini that produce caustic-calcined magnesite; and a refractory plant at Kalives. Production capacity is 120 ktpy of caustic-calcined magnesite, grading between 88% and 95% MgO , and 100 ktpy of dead-burned magnesite, grading from 85% to 96% MgO .

India

India, a traditional supplier of crude and caustic-calcined magnesite, now produces mainly dead-burned magnesite for its own refractory industry, although small quantities of caustic-calcined magnesite are still produced. Deposits in the southern Salem district of Madras State are cryptocrystalline. The magnesite is of high quality but is mixed with serpentine and requires beneficiation to obtain optimum purity. Deposits in northern India in the Almora district, Uttar Pradesh, are crystalline. Here the ore is white to yellowish in color and produces a sinter in the range of 90% MgO . The Almora deposits are becoming depleted and beneficiation has become more necessary; hand sorting alone does not produce commercial tonnages

or quality (Clark 1983). Approximately 10 companies operate magnesite mining and calcining facilities in India with a total capacity of 270 ktpy; most of this is dead-burned magnesite, but it includes 25 ktpy of caustic-calcined production capacity.

Iran

In eastern Iran, more than 1 Mt of cryptocrystalline magnesite has been reportedly identified in a 20-km-long series of deposits located 50 km southeast of Birjand. Iranian Refractories Procurement and Production Co. operates a 30-ktpy dead-burned magnesite plant in Sarbisheh. Total reserves of magnesite in Iran have been estimated at 5 Mt (Sargheini 2003).

Nepal

According to the Nepal Department of Mines and Geology, ore reserves at the Kharidhunga deposit in Dolkha District, about 110 km northeast of Kathmandu, the national capital, were estimated at 180 Mt, of which 66 Mt was refractory-grade magnesite. Of this 66 Mt, 25 Mt was high-grade recoverable reserves. The Kharidhunga deposit is a crystalline type. The MgO content of ore averages 88% with a maximum 4.5% each for silicon dioxide (SiO_2) and ferric oxide (Fe_2O_3), and 1% each for aluminum oxide (Al_2O_3) and CaO. Mining at Kharidhunga stopped in 1990 because of technical problems at a processing plant producing dead-burned magnesite.

North Korea

Little information is available about the geology of North Korean magnesite deposits, but annual production of crude magnesite has been reported to be in excess of 1 Mt. The principal magnesite deposits are located in Hamgyŏng-namdo and average, on a crude basis, 45% MgO. Korea Magnesia Clinker Industry Group operates three mines and plants in Hamgyŏng-namdo that produce primarily dead-burned magnesite, although small quantities of caustic-calcined magnesite are produced. An open-pit mine has a capacity of 1.3 Mtpy, and two underground mines have a combined capacity of 1.2 Mtpy. The combined capacity of the three plants is estimated to be 1.15 Mtpy. The company produces four grades of dead-burned magnesite. The Grade A product contains a minimum of 90% MgO and maximums of 4.5% SiO_2 and 2% CaO (Anon. 2003b). A small portion is exported, but the majority is used by the country's steel industry.

Russia

Russia has the largest share of magnesite in the Commonwealth of Independent States (CIS), estimated to be about 90% of the total. Resources for the CIS have been estimated to be 800 Mt. The largest magnesite deposits are in the Irkutsk area—the Savinsk deposit and the Onotsk deposit. The Savinsk deposit is unmined, and the Onotsk deposit, which consists of talc-altered magnesite, is currently being mined for talc. The Satkinsk group of deposits, consisting of the Satkinsk, Nikol'sk, and Berezhovsk deposits in the Chelabinsk region, is being mined by the largest magnesite-producing company in Russia—JSC Kombinat Magnazit. This company has the capacity to produce 2.4 Mtpy of dead-burned magnesite, most of which is consumed in-house for refractories production; 100 ktpy of caustic-calcined magnesite; and 24 ktpy of fused magnesite. There are three significant deposits of magnesite in the Krasnoyarsk region—the Talsk, Verkhoturovsk, and Kardakansk deposits. Also in the Krasnoyarsk region, the Severo-Angarsk periclase plant is consuming about 30 ktpy of magnesite from the Kirgiteisk deposit (Troitsky 1997).

In addition to magnesite, the Kul'durskoe brucite deposit in Khabarovsk region contains about 4 Mt of brucite. It has been mined since 1971 and produces about 50 ktpy of ore (Anon. 1996).

Besides Russia, Ukraine and Kazakhstan have magnesite deposits. The Pravdinsk deposit in the Dnepropetrovsk region, Ukraine, contains about 70 Mt of magnesite. This material, however, is talc altered, and preliminary concentration is needed to produce material suitable for the refractory industry. Geological exploration has not been completed at the Mar'yanovsk magnesite deposit in eastern Kazakhstan, so no resource data are available for this deposit.

Serbia and Montenegro

Deposits of magnesite in Serbia and Montenegro extend into Bosnia and Herzegovina. The material is mined in both underground operations and in open-pit quarries; limited production precludes significant exports. These magnesite deposits are hydrothermal sedimentary and hydrothermal vein types. Vein-type deposits are located in Sumadija, Goleš, Dubovac, and Ibar. All the ore requires beneficiation—in this case, heavy media separation—in order to produce commercial quality concentrate (Petrov et al. 1980). Magnesite resources in Kosovo are estimated to be 4.5 Mt, of which 1.7 Mt is calculated reserves.

The principal magnesite mines, operated by Magnohrom Kraljevo, are underground mines at Užice and Čačak in Serbia and Montenegro, respectively. Magnesite is shipped to a magnesite plant in Kraljevo with a capacity of 160 ktpy of dead-burned magnesite and 40 ktpy of caustic-calcined magnesite. Because of the conflict in the 1990s, production at this plant has been significantly below annual capacity.

Slovakia

Slovakia has deposits of magnesite in Košice, Jelšava, and Lovinobaňa. In Jelšava, magnesite is associated with carbonate rocks in an irregularly shaped deposit about 4,000 m long by 1,000 m thick (Grend 1994). Slovenské Magnesitové Závody a.s. Jelšava (SMZ) operates mines in Dúbrava, Jelšava, and Mútnik, Hačava. Material from the semi-ores, a long with imported magnesite, feeds SMZ's 375-ktpy dead-burned magnesite plant in Jelšava. Slovmag a.s. Lubeník operates a mine and a 90-ktpy captive dead-burned magnesite plant in Lubeník.

South Africa

South Africa has been a producer of magnesite for more than 20 years, but the output has been somewhat irregular. The problem is with the mining; the ore occurs in pockets at irregular intervals. South Africa's economically viable deposits of magnesite occur as weathering products of rocks with high magnesium contents. The main magnesite deposits are in Mpumalanga and Limpopo provinces—the Malelane area, in the vicinity of Lydenburg, and an area to the north of the Soutpansberg and in the Burgersfort and Giyani districts. South Africa has two operating magnesite mines, Strathmore (owned by Chamotte Holdings [Pty] Ltd.) at Malelane, Mpumalanga and Syferfontein (owned by Syferfontein Calcite [Pty] Ltd.) in Soutpansberg district, Limpopo. Most of the magnesite is sold as crude material to local farmers for fertilizer applications, but the two operations can produce 12 ktpy of caustic-calcined magnesite (Ratlabala 2003). The reserves of magnesite in South Africa are estimated at 2.5 Mt, and total resources are estimated at 18 Mt (Agnello 2003).

Spain

Spain's magnesite deposits are principally located in Navarra Province, near the French border. The magnesite rocks are composed of lens-shaped crystals arranged in black and white bands (Lugli et al. 2000). There are also smaller deposits in northwest Spain. The total

production capacity is approximately 600 ktpy of crude magnesite (Harris 2001). Magnesita Navarras SA mines magnesite from a deposit at Eugui and has the capacity to produce about 100 ktpy of caustic-calcined magnesite and 70 ktpy of dead-burned magnesite (82%–90% MgO). Magnesitas de Rubian SA produces about 80 ktpy of caustic-calcined magnesite from a magnesite deposit in Lugo. The majority of both producers' caustic-calcined magnesite is destined for the agricultural market.

Turkey

Turkey has both crystalline and cryptocrystalline deposits of magnesite. The principal crystalline deposit is in the Black Sea region. The more important cryptocrystalline deposits, which are in the Eskisehir and Kutaya regions, are of the vein-filling type (Zedef et al. 2000). Another cryptocrystalline magnesite deposit is at Salda Lake in southern Turkey, approximately 150 km northwest of the port of Antalya and near the town of Yesilova. Here, magnesite is mixed with mud and occurs as dunes and as lumps on the lake-shore. The magnesite generally is not compacted and has a specific gravity of 1.60 to 1.80 g/cm³ (Schmid 1989).

Kümaş-Kütahya Magnesite Works Corporation operates a 350-ktpy mine at Kütahya that feeds a 180-ktpy dead-burned magnesite plant. Magnesit AŞ (in the Eskisehir region) can produce about 140 ktpy of dead-burned magnesite from magnesite from its own mines and from imported material. A third company, Konyu Selçuklu Krom Magnezit Tuğla Sanayi AŞ, mines magnesite at Cayirbagi, Helvacibaba, and Konya, and produces dead-burned magnesite for its internal production of refractories.

Other Locations

Two locations in Saudi Arabia containing magnesite deposits have been identified. The first, located in the Zarghat area, about 400 km northeast of Madinah, contains an estimated 1.6 Mt of magnesite. The other major magnesite site is in Jabal Rukman, about 180 km southeast of Madinah (U.S.–Saudi Arabian Business Council 2000). The country is investigating the production of 20 ktpy of fused magnesite from the Zarghat deposit.

Other, apparently minor, magnesite deposits have been reported to occur in Bolivia, Bulgaria, Colombia, Egypt, Guatemala, Kenya, Pakistan, the Philippines, and Zimbabwe.

SYNTHETIC MAGNESIA

Before 1938, the naturally occurring mineral magnesite was essentially the source of all refractory magnesite. Since that time, the manufacture of refractory-grade magnesite and caustic-calcined magnesite from sources other than natural magnesite has steadily increased in importance. Today, approximately two thirds of refractory-grade magnesite used in the western economic countries comes from synthetic magnesite sources. Several basically different methods for production of magnesite from nonmagnesite sources have been studied, and at least four have operated commercially. All involve the calcination of either magnesium hydroxide or magnesium chloride. Magnesium hydroxide may be obtained as a precipitate from magnesium-rich solutions or as a residue remaining after the lime fraction of calcined dolomite is removed as a soluble compound by reaction with solutions of ammonium chloride or hydrogen sulfide. Magnesium chloride may also be obtained as an end liquor after solar concentration of solutions of natural brines for production of salt or potash, or from well brines.

The choice of suitable sites for seawater magnesite plants is limited. Large land masses can cause the seawater to be diluted because of freshwater runoff and tidal action. Other factors, such as coastal topography, a availability of high-purity limestone or dolomite, fuel

source, and market location, are closely studied before a site is selected.

There are more than 20 plants around the world producing refractory magnesite and caustic-calcined magnesite from magnesium hydroxide. In these plants, magnesium hydroxide is obtained by precipitation from solutions such as seawater, seawater bitterns, inland well brines, or end liquors from other chemical processes. The following discussion highlights the larger foreign operations.

Ireland

Premier Periclase Ltd. operates a 90-ktpy plant in Drogheda to produce caustic-calcined and dead-burned magnesite from seawater. The company also produces magnesium hydroxide, and with recent capital investment has begun broadening the markets that it serves, adding the rubber and plastics industries to its traditional chemical and agricultural markets.

Israel

In 1969, Dead Sea Periclase Ltd. began producing dead-burned magnesite from Dead Sea brine, using the Aman process at a plant in Mishor Rotem. The Aman process uses concentrated magnesium chloride from the Dead Sea as a feedstock and does not use lime or dolomite as a reagent. As a result, the magnesite is 99.5% pure and does not include impurities such as SiO₂, Fe₂O₃, and Al₂O₃ that lime or dolomite leaves in the product. The purity of the product has allowed Dead Sea Periclase to enter the specialty magnesite market in addition to traditional applications. The plant has the capacity to produce 70 ktpy of magnesite—60 ktpy of dead-burned and 10 ktpy of caustic-calcined. The plant also produces fused magnesite, magnesium hydroxide, and magnesium chloride.

Italy

Two seawater magnesite operations in Italy have closed in recent years. The most recent closure was Cogema SpA's 85-ktpy operation in Priolo, Iracusa, Sicily, which shut down in March 2003; it is unclear if the plant will reopen.

Japan

Ube Material Industries Ltd. can produce 50 ktpy of caustic-calcined magnesite and 250 ktpy of dead-burned magnesite from seawater at its plant in Ube City. The company also recovers magnesium hydroxide and ships magnesite to Tatehō Dead Sea Fused Magnesite (Mishor Rotem, Israel) for fused magnesite production.

Mexico

Química del Rey SA de CV produces caustic-calcined and dead-burned magnesite from natural subsurface brines, which are pumped from a depth of 10 to 20 m through wells at Laguna del Rey, Coahuila. Total production capacity is 15 ktpy of caustic-calcined magnesite and 95 ktpy of dead-burned magnesite.

Netherlands

Nedmag Industries Mining and Manufacturing BV recovers magnesium chloride brine from a bischofite salt formation at a depth of about 1,500 m in the northern part of the Netherlands. The magnesium chloride is used to produce 150 ktpy of dead-burned magnesite, 8 ktpy of caustic-calcined magnesite, and magnesium hydroxide at the company's Veendam plant.

Other Locations

In addition to the plants described previously, small seawater magnesite plants exist in France, the Republic of Korea, Ukraine, and the United Kingdom.

TECHNOLOGY

Exploration

The search for deposits of any type of magnesite is based on considerations involving the probable origin of different types of magnesite. In the case of crystalline magnesite, possible locations of deposits are areas of limestone or dolomite terrain that have been subjected to folding or igneous activity. In the case of cryptocrystalline magnesite, possible locations are areas of ultrabasic rocks that show extensive alteration to serpentine. Thus, in either case, the search can be confined within the boundaries of areas that show evidence of structural or igneous activity; for instance, an area such as the midwestern United States would not be favorable for the occurrence of magnesite despite its large deposits of limestone and dolomite.

Magnesite formations are generally more resistant to weathering than associated formations; bold outcrops frequently characterize magnesite deposits. This is very evident in the Baja California peninsula where the magnesite stands out as caps on the mountains. Outcrops are sampled by surface chipping and shallow trenching. Sedimentary magnesite is difficult to recognize because it has no clearly distinguishing physical features or characteristic geologic associations.

Following preliminary investigations, a diamond drill program may be carried out to assess the commercial potential of the deposit. The formal final evaluation is based on the size and location of the deposit and the quantity and distribution of undesired minerals containing silica, lime, iron oxide, and alumina. Tests to determine whether the impurities can be removed by ore dressing must be part of the evaluation. To be commercially acceptable, magnesite should contain at least 95% magnesium carbonate, an amount that, depending on the accessory oxides, would result in a dead-burned product containing 90%–94% MgO. Refractory-grade magnesia of that quality would have some demand at the lower end of the price scale. The growing demand is for even higher MgO content, and this places increased emphasis on the need to beneficiate the ore.

Mining

Magnesite mining and processing practices of varying forms and complexity are found in many places around the world. The type of the deposit dictates the method of mining. Large, massive, near-surface deposits are usually worked by open-pit methods. Narrow and deep deposits are worked by underground drifts and stopes. The mined ore is rarely shipped or used in crude form. It is processed near the mine site to yield magnesia products. Invariably some degree of sorting or beneficiation is applied to the ore prior to heat treatment.

Processing

Dead-Burned and Caustic-Calcined Magnesia

In the production of refractory magnesia and caustic-calcined magnesia, magnesite is delivered from the mine to a crushing plant where it is crushed in three stages. Depending on the grade of the ore, the crushed material is conveyed to one of three storage piles. Each storage pile feeds a separate production circuit—the flotation plant, the heavy-medium separation plant, and the rotary kiln plant. Concentrates from the flotation and heavy-medium separation circuits also feed the rotary kiln plant.

The kiln plant feed goes into two separate circuits for calcination. One, for the production of dead-burned magnesite, uses either rotary kilns or shaft furnaces; the other, for caustic-calcined magnesite, uses hearth furnaces or rotary kilns. Some of the raw feed is mixed with flue dust and briquetted before being dead-burned in the rotary kiln. Two classes of refractory magnesia are made: brick grade and maintenance grade.

Table 3. Typical composition of Michigan brine and seawater (grams per liter)

Component	Michigan Brine	Seawater
Magnesium chloride (MgCl ₂)	8.2	4.176
Magnesium sulfate (MgSO ₄)	0	1.668
Magnesium bromide (MgBr ₂)	0	0.076
Calcium chloride (CaCl ₂)	13.64	0
Calcium sulfate (CaSO ₄)	0	1.268
Sodium chloride (NaCl)	5.45	27.319
Potassium chloride (KCl)	0.48	0
Potassium sulfate (K ₂ SO ₄)	0	0.869
Bromine gas (Br ₂)	0.2134	0
Specific gravity	1.264	1.024

Dolomite and brucite are processed in a similar manner. After primary crushing, raw, crushed dolomite is delivered to iron and steel plants, where it is calcined and used as dead-burned dolomite. Brucite is beneficiated in a heavy-medium plant for use as a refractory material.

When seawater or well brine is used as the feed for producing magnesia, dissolved carbonate and sulfate levels are reduced so insoluble calcium compounds do not precipitate with the magnesium hydroxide. To accomplish this reduction, the brine or seawater is either treated with slaked lime or acid to precipitate the carbonates and sulfates as calcium compounds. The filtered, treated solution is then mixed with either dry or slaked lime to precipitate magnesium hydroxide. The resulting magnesium hydroxide slurry is concentrated with thickeners and washed with fresh water in a countercurrent system, then filtered. The filter cake is either directly calcined to produce refractory or caustic-calcined magnesia, or it is calcined and pelletized before dead-burning to give proper size and density characteristics.

Magnesium Hydroxide

Magnesium hydroxide is recovered from seawater or brines by precipitating the dissolved magnesium as magnesium hydroxide with the addition of dolime (CaO•MgO). Because the composition of seawater is slightly different from that of Michigan brine (Table 3), removal of impurities or salable by-products is slightly different.

Michigan brine is pumped from 850 m below the earth's surface. Bromine is removed from the brine by heating followed by chlorination with chlorine gas, which replaces the dissolved bromine with chlorine, producing bromine gas (Br₂). The debrominated solution is mixed with preheated, slaked dolime to precipitate the magnesium hydroxide in settling tanks. The remaining calcium chloride solution is concentrated and can then be sold as a 32% to 45% liquor for a variety of applications.

To recover magnesium hydroxide from seawater, the seawater is first screened to remove any debris before being treated with dolime to remove any dissolved carbonate as calcium carbonate. After calcium carbonate is precipitated, the solution is treated further with sulfuric acid to remove any remaining calcium bicarbonate as calcium sulfate. The solution is then seeded with magnesium hydroxide and pumped to thickeners where the magnesium hydroxide slurry is concentrated. The slurry is filtered to produce a filter cake containing about 50% solids. This material can be sold as a hydroxide or calcined to produce either dead-burned or caustic-calcined magnesia.

Table 4. Magnesium chloride brine chemical composition and characteristics

Magnesium chloride (MgCl ₂)	28.0–35.0 wt %
Chlorine (Cl)	19.8–27.0 wt %
Magnesium (Mg)	6.8–9.2 wt %
Sulfate ion (SO ₄)	1.2–3.5 wt %
Sodium (Na)	0.2–1.0 wt %
Potassium (K)	0.1–0.8 wt %
Lithium (Li)	0.1–0.2 wt %
Bromine (Br)	0.1–0.2 wt %
Iron (Fe)	5–10 ppm
Specific gravity	1.27–1.36 g/L
Bulk density	11 lb/gal

Adapted from Reilly Industries, Inc. 1997.

Magnesium Chloride

To recover magnesium chloride from brines, using the Great Salt Lake brines as an example, the water is pumped to a series of solar evaporation ponds where water evaporates to concentrate the brine. The first salt to precipitate as the water evaporates is sodium chloride. The next group of salts to precipitate is a mix of double salts containing potassium and magnesium. Depending on brine concentration, temperature, and other factors, kainite (MgSO₄•KCl•3H₂O), schoenite (MgSO₄•K₂SO₄•6H₂O), and carnallite (KMgCl₃•6H₂O) may be precipitated. Sodium sulfate is then precipitated from the cooled brine in the winter (even though it is no longer harvested for sale). The final product remaining dissolved in the brine is magnesium chloride. In general, equilibrium is reached at about 35% magnesium chloride (MgCl₂) concentration by weight in the brine. Although most of the sodium and potassium have been removed from the brine at this stage, it still contains some dissolved sulfate. The purity of this brine is sufficient for some applications, but if necessary, it may be purified further. Purified brine then may be further processed to produce the hexahydrate solid formula. The overall production cycle takes about 2 years to complete (Anon. 1984). Table 4 gives a typical analysis of Great Salt Lake brine.

Magnesium Sulfate

Synthetic magnesium sulfate in the United States is normally produced by reacting magnesium oxide, hydroxide, or carbonate with sulfuric acid followed by crystallization. Anhydrous magnesium sulfate can be manufactured only by dehydration of a hydrate; crystallization from an aqueous solution is not possible.

MARKETING

Uses

Dead-Burned Magnesia

Refractory magnesia represents the largest tonnage use of magnesium in compounds. The iron and steel industry is the largest consumer of these products in the United States and most other magnesia-consuming countries. Dead-burned magnesia from magnesite, sea water, or well and lake brines is used as a major constituent in metallurgical furnace refractory products. Steel furnaces, which use 70% of the total, are the largest consumers of refractory products. Furnaces used for cement and lime (7%), ceramics (6%), glass (4%), chemicals (4%), and nonferrous metals production (3%) are other consumers of magnesia-based refractories. Other applications account for the remaining 6% (Kandianis and Kandianis 2002).

Although magnesia refractories can be formed into a variety of shapes, bricks are the most common. Magnesia can be combined with other materials to form bricks with specific characteristics that are used in specific areas of a furnace or as ladle linings. The most common use for magnesia brick is as wear and permanent linings in electric arc furnaces (EAFs) and as a permanent lining in BOFs. Magnesia-carbon brick and MgO-CaO brick are used as wear linings in BOFs, EAFs, and steel casting ladles. Directly bonded magnesia-chrome brick is used in secondary steelmaking furnaces.

Caustic-Calcined Magnesia

Caustic-calcined magnesia has uses in many market segments. In water treatment, magnesia is used to remove silica and heavy metals from industrial wastewater. It is also used as a neutralizing agent for some wastewater streams. Caustic-calcined magnesia is used for removal of sulfur dioxide (SO₂) from industrial flue gases; the magnesium oxide reacts with the SO₂ to form magnesium sulfate. Magnesia competes with calcium compounds in this application. Annually, environmental applications average between 35% and 40% of U.S. shipments of caustic-calcined magnesia.

Magnesia is also used in agricultural applications for animal feed and fertilizer; in the United States, these applications represent about 20%–25% of the total annual caustic-calcined magnesia shipment. Magnesium serves as a structural part of the chlorophyll molecule, a compound necessary for plant photosynthesis. Without sufficient magnesium, either from the soil or from fertilizer application, plants can die. Grazing ruminants, such as cattle and sheep, require magnesium in their diet to guard against hypomagnesia, also known as grass tetany, a potentially fatal disease.

Caustic-calcined magnesia is used as a precursor to other magnesia chemicals, including chlorides, nitrates, and epsom salts. The accounts for about 35% of annual U.S. magnesia shipments.

An important use of caustic-calcined magnesia is in the production of magnesium oxychloride and oxysulfate cements, which are used primarily as flooring in industrial and institutional buildings. Fused and boron-free magnesia or periclase are used for insulation of heating elements in electric furnaces and appliances.

Caustic-calcined magnesia is used in the production of rayon, fuel additives, and rubber. Caustic-calcined magnesia is used to produce magnesium acetate, which is used for neutralization purposes in producing rayon fiber. Caustic-calcined magnesia is a starting material for the production of magnesium-overbased sulfonates, which are used as acid acceptors and sludge dispersants in crankcase lubricating oils and as a fuel additive. Magnesium oxide also may be injected into oil-fired utility boilers where it reacts with vanadium salts to form a magnesium vanadate; this alleviates slagging and corrosion problems encountered when using high-vanadium fuels. In water-based oil-well drilling muds, magnesia is used as a buffer, for viscosity control, and as a corrosion inhibitor. In the rubber industry, caustic-calcined magnesia is used as a vulcanizing agent in the curing of rubbers and elastomers.

In the food industry, caustic-calcined magnesia is used in sugar refining for neutralization of raw cane and beet juices and to reduce scaling in juice heaters, evaporators, juice lines, and other equipment. U.S. Pharmacopoeia (USP)-grade caustic-calcined magnesia can be used in pharmaceutical applications.

Magnesium Hydroxide

After discounting the portion of magnesium hydroxide that is used to produce dead-burned magnesia, the largest use for magnesium hydroxide in the United States is for environmental applications. This portion of the market, which includes industrial water treatment, heavy metals removal, and flue-gas desulfurization, accounts

for about 60% of the total U.S. consumption. For water treatment, magnesium hydroxide is supplied as a suspension containing about 58% solids, and it primarily is used to lower the pH of acidic solutions. In this market, it competes with other acid-neutralizing compounds, the most common being lime and caustic soda (NaOH). Magnesium hydroxide has advantages and disadvantages when compared to the other materials in this use. One of the advantages is that it is a pH buffer, and wastewater treated with it will not exceed a pH of 9.5 even if excess magnesium hydroxide is added. In contrast, excess addition of lime can raise the pH to 12, and excess caustic soda addition can raise the pH to 14. In these cases, back additions of acid are necessary to lower the pH. Magnesium hydroxide also has a higher basicity per unit added than either lime or caustic soda; for equivalent neutralization, 0.72 t of magnesium hydroxide can replace 1 t of lime. Magnesium hydroxide is better than lime or caustic soda at removing some metals such as lead and trivalent chromium. Metal hydroxides that are precipitated with magnesium hydroxide rather than caustic soda or lime tend to form larger crystals, resulting in lower sludge volumes and, hence, lower disposal costs. The solids formed through precipitation by magnesium hydroxide have a cakelike consistency, rather than the gel-like consistency of solids formed by caustic soda precipitation; the cake is easier to handle (Wajer 1994).

One principal disadvantage of magnesium hydroxide is its higher cost compared to that of other water treatment materials. Another disadvantage is its slower reaction rate, particularly when precipitating high concentrations of metals (greater than 2,000 ppm) or neutralizing weak or organic acids. Most treatment systems in use today were originally designed to use lime or caustic soda, and as a result of magnesium hydroxide's slower reaction time, there may not be enough residence time in the system. In some cases, users must reconfigure their systems when switching to magnesium hydroxide.

Magnesium hydroxide slurry also competes with magnesium oxide where there are large neutralization requirements. Magnesium oxide has about 2.5 times as much neutralizing capability as magnesium hydroxide per unit volume, and transportation costs for the oxide are generally lower than those for the hydroxide slurry. In addition, existing lime neutralization systems may be more easily converted to use the magnesium oxide powder rather than the hydroxide slurry.

In flue-gas desulfurization, magnesium hydroxide is used in place of lime in a few applications. Most of the processes designed for industrial gas scrubbing use lime or calcium in some form. Scrubbing with lime produces gypsum products, which need to be landfilled in most cases. The volume of these waste products may be greater than the original waste volume, so lime may not be appropriate for all scrubbing applications. In these instances, magnesium hydroxide may be used. Landfilling, however, may not be as much of a problem in the future for lime scrubber wastes because the by-product gypsum can be used in wallboard.

The second largest use for magnesium hydroxide is as a precursor for other magnesium chemicals, which accounts for about 20% of annual U.S. consumption. About 5% of magnesium hydroxide is used in pharmaceuticals. The pharmaceutical grades of magnesium hydroxide include a 100% $\text{Mg}(\text{OH})_2$ powder used in antacid tablets and a 30% $\text{Mg}(\text{OH})_2$ paste used in liquid antacids such as milk of magnesia.

Flame retardants represent about 3% of the total magnesium hydroxide consumption in the United States. Like magnesium carbonate, magnesium hydroxide can replace alumina trihydrate in some flame retardants. Both alumina trihydrate and magnesium hydroxide function as flame retardants by releasing water vapor in an endothermic reaction that diverts the heat away from the flame,

thereby reducing the formation of combustible gases. Alumina or magnesia remaining after the water is released is believed to have a high surface area available for absorbing smoke. Although the properties of alumina trihydrate and magnesium hydroxide are similar, magnesium hydroxide has higher temperature stability. Magnesium hydroxide begins to decompose at about 330°C, compared with about 200°C for alumina trihydrate. This higher temperature stability makes magnesium hydroxide more attractive for specific flame retardant applications. Some thermoplastics, such as polypropylene or nylon-vinyl, require temperatures in processing that are high enough to begin alumina trihydrate decomposition. In addition, the high processing speed of lines that produce plastic insulation for wire and cable generates enough friction to begin alumina trihydrate decomposition. In these cases, magnesium hydroxide is the flame retardant of choice.

Magnesium Chloride

The largest use for magnesium chloride brine is as a suppressant for dust on dirt roads, construction sites, unpaved parking lots, mines, and quarries. A corrosion inhibitor may be added to the brine to reduce corrosion on structures, such as steel surfaces, that are associated with the sites where the brine is used. The inhibitor forms a protective coating so that the brine will not corrode metal surfaces. Magnesium chloride brine may also be used to melt ice on road surfaces, sometimes in conjunction with an abrasive such as sand. Brines may be used to make oxychloride flooring cements, known as Sorel cements. These are vermin-resistant flooring cements that are used in industrial buildings. Brines also have applications in oil-well completion fluids, as a component of some herbicides, and in regeneration of ion-exchange resins.

Magnesium chloride hexahydrate is almost exclusively used for melting ice. It is used in conjunction with, or in place of, salt for removal of ice and snow from sidewalks and roadways. Magnesium chloride has a lower freezing point than salt and is generally less corrosive to asphalt and cement, but it is significantly more expensive. In most cases, salt is used as the major melting agent for ice and snow, but if the surface that is being treated is expensive to maintain, the additional cost for magnesium chloride can be justified.

Magnesium Sulfate

Natural and synthetic magnesium sulfates have a wide array of end uses. The largest use for magnesium sulfate in all forms is for consumer goods. About 30% of magnesium sulfate is used in food additives and pharmaceuticals. Magnesium sulfate heptahydrate—Epsom salts—is used for mineral baths and in medicine as a cathartic and analgesic soaking agent for bruises, sprains, localized inflammations, and insect bites. Magnesium sulfate is used as a micronutrient in some food products, and it is used in the production of high-fructose corn syrup.

Industrial uses account for about 25% of U.S. magnesium sulfate demand. The primary component of industrial applications is the use of magnesium sulfate as a precursor to other chemicals. It also is used in drying and flocculation applications and in catalyst preparation.

Animal feeds and fertilizers represent about 20% of the U.S. market for magnesium sulfate. Most end uses for magnesium sulfate use synthetically produced material because of its higher purity. Purity requirements for animal feeds and fertilizers are not as stringent, so they mainly contain the natural minerals, which are imported into the United States. The most effective way of preventing grass tetany is to provide magnesium to the pasture through fertilization. Magnesium may also be supplied in the form of Epsom salts or kieserite that is added to the feed or drinking water.

Pulp and paper processing accounts for about 15% of magnesium sulfate use in the United States. Magnesium sulfate is used by kraft pulp mills that use oxygen delignification on soft woods, but it is also used in conjunction with sodium silicate to increase the life of hydrogen peroxide in oxygen-based bleaching processes. Miscellaneous uses, which represent about 10% of magnesium sulfate demand, include adhesives, textiles, matches, metal plating, photographic solutions, rubber coagulation, refractory bonding agents in bricks, and oxysulfate cements.

Grades and Specifications

Specifications for magnesia, including chemical composition, bulk density, particle size, and loss on ignition, are generally set by the consumer for a specific application. Refractory magnesia composition depends on the area of the furnace in which the material is to be used. Magnesia produced from magnesite can contain between 88% and 98% magnesia, with varying quantities of alumina, calcium, iron, and silica impurities. Synthetic magnesia is normally purer than natural magnesia, containing between 92.0% and 99.5% magnesia, with smaller quantities of the same impurities found in natural magnesia. Synthetic magnesia may also contain boron impurities. Most fused magnesia contains greater than 94% magnesia. Some individual specifications are shown in Table 5. As a general rule, dead-burned magnesia containing greater than 97% MgO, with a bulk density of 3.40 g/cm³, and a periclase crystal size that is greater than 120 m, is called high-purity magnesia. Countries that supply this grade include Australia, Ireland, Israel, Japan, Mexico, the Netherlands, and the United States. Dead-burned magnesia from China, Greece, Slovakia, Spain, and Turkey supplies the low- to medium-purity market.

Prices

Magnesia pricing is relatively stable; quoted prices change infrequently. Table 6 shows year-end 2003 prices as quoted in *Chemical Market Reporter*. Prices for Chinese- and European-produced magnesia, as quoted in *Industrial Minerals*, are also shown. These prices are producer list prices, and large customers may receive discounts from these price levels. Because of the variety of grades available, caustic-calcined magnesia prices vary significantly depending on application. Natural caustic-calcined magnesia in bags is quoted at about \$400/t, whereas the high-end rubber and plastic grades of caustic-calcined magnesia were priced at about \$700/t. Recent wide swings in natural gas prices have caused producers to increase pricing for their magnesia products to compensate for higher energy costs. Buying decisions for caustic-calcined magnesia are price-based because of competition from competing mineral products such as caustic soda or dolomite and are significantly influenced by transportation costs.

ECONOMIC OR COMPETITIVE FACTORS

Tariffs and Depletion Provisions

The tariffs on magnesia and magnesium compounds for countries with which the United States has normal trade relations (NTR) are shown in Table 7. In addition, because of trade agreements, some countries have special tariff rates; these are also given in the table. Tariff rates have been established for countries with non-NTR with the United States; in 2003, these countries were Afghanistan, Cuba, Laos, North Korea, and Vietnam. Because there is no appreciable trade between the United States and these countries, the non-NTR tariff rates are not shown.

Depletion allowances have been established for some domestic and foreign ores of magnesium and its compounds. Magnesium

chloride from brines, wells, or saline perennial lakes within the United States has a depletion allowance of 5%. The depletion allowance for both domestic and foreign ores of dolomite and magnesium carbonate is 14%. Depletion allowances for other ores are as follows: brucite, 10% (domestic and foreign); and olivine, 22% (domestic) and 14% (foreign).

By-products and Coproducts

Because a significant percentage of magnesium compounds is extracted from saline solutions and evaporites, salt and bromine are major coproducts recovered during magnesium compound recovery. In addition, potassium compounds and gypsum can be extracted from sediments of seawater evaporite deposits. Sodium, lithium, iodine, and strontium compounds can be obtained from sediments and near-surface brines formed by inland bodies of water. Iodine and calcium compounds are generally extracted from well and lake brines. Bromine is recovered as a by-product of processing Michigan brines.

Costs

Because of the diverse nature of the processes used to produce magnesia and the variety of raw materials that can be used, costs vary widely from operation to operation. Wilburn (1986) provided estimates of costs to produce caustic-calcined and dead-burned magnesia. Although somewhat dated, the report gives some basic information about the relative costs of each raw material source. In general, seawater was the highest cost source for magnesia recovery, which is not surprising considering that it has the lowest magnesium concentration of any of the most commonly used sources. Production costs for caustic-calcined magnesia were generally lower than those for dead-burned magnesia, regardless of the source material, mainly because of lower energy costs associated with the lower calcining temperature. For dead-burned magnesia, energy costs represent 58% to 71% of the total operating cost, compared with 37% to 59% for caustic-calcined magnesia. Sale of by-product materials that can be recovered from a seawater or brine operation helps to offset some of the production costs.

Substitutes

There are few substitutes for dead-burned magnesia in refractory applications. In some cases, alumina, chromite, and kyanite may substitute, but with a loss of performance. Caustic-calcined magnesia competes with a variety of materials, depending on the application. In some cases, caustic-calcined magnesia has entered markets that have been dominated by other materials, so it is considered a substitute. In environmental applications, it competes mainly with lime and caustic soda in wastewater treatment, and with lime and limestone for stack-gas scrubbing. It also competes with magnesium hydroxide in these applications. In fire-retardant applications, magnesium hydroxide is a competitor to alumina trihydrate.

REGULATORY AND ENVIRONMENTAL CONSIDERATIONS

Magnesite and dolomite can normally be mined with minimal interference with other land use. Mine drainage from open-pit or underground operations does not contribute significantly to stream pollution because the drained areas usually contain no significant amounts of soluble materials. Dust collectors and wet scrubbers are used to control stack-gas dust emissions from plants calcining and dead-burning dolomite, magnesite, and magnesium hydroxide.

In magnesia plants based on seawater, the water is returned to the ocean after the magnesia is removed. Recent innovations have decreased the turbidity of the effluent, resulting in minimal changes to the ocean environment. None of the discharges from either natural

or synthetic magnesias plants has a noxious quality, and their appearance can be made acceptable with modern treatment methods.

Most magnesium compounds are treated as nuisance-causing dusts in the workplace. The American Conference of Governmental Industrial Hygienists has established threshold limit values (TLVs) for magnesium oxide fumes and magnesium carbonate. The TLV for both substances has been established at 10 mg/m³. TLVs for magnesium chloride and magnesium sulfate have not been established. The Occupational Safety and Health Administration has set permissible exposure limits (PELs) for magnesium carbonate and magnesium oxide fumes. The PEL for magnesium oxide fumes was established at 15 mg/m³ (total particulate), with a PEL of 5 mg/m³ for the respirable particulate (International Programme on Chemical Safety 1994b). The PEL for magnesium carbonate (magnesite) has been set at 15 mg/m³ (International Programme on Chemical Safety 1994a). If magnesite contains more than 1% crystalline silica, the TLV and PEL for the material can be much lower because of the potential danger in long-term exposure to crystalline silica.

Because of the chromium content in the material, magnesia-chrome bricks must be disposed of as a hazardous waste if an extract from a representative sample contains total chromium at a concentration greater than or equal to 5.0 mg/L. The waste can be treated by chemical leaching or washing to dilute the concentration, but these options are costly, and if washing is used, the wastewater must also be treated. Another alternative for treatment is high-temperature reprocessing, but few firms have the treatment facilities necessary for this operation (Kendall 1994).

OUTLOOK AND FUTURE TRENDS

Overall, worldwide refractory magnesia consumption is influenced by several trends:

- Consolidation within the refractories industry
- Decreasing consumption because of technologic development in the steelmaking industry
- Production of higher quality refractory materials, leading to longer furnace-lining lives
- A shift from using BOFs to using EAFs in steelmaking, leading to increased use of basic refractories
- A greater demand for high-purity dead-burned magnesia with a bulk density greater than 3.40 g/cm³ and a crystal size greater than 120 µm

China has become the dominant world supplier of dead-burned magnesia in the low- to medium-grade markets. As a result, many producers of these grades have closed because they cannot compete with the lower priced Chinese material (Table 6).

In the United States, the dead-burned magnesia market is likely to continue to be dominated by imports, especially of magnesia from China. Within the past 5 years, the United States has lost three producers of dead-burned magnesia and is left with only one. In addition, the steel production industry has contracted, leaving fewer markets for dead-burned magnesia. For caustic-calcined magnesia, however, the future appears to be a little brighter. Water treatment usage of magnesia and magnesium hydroxide is growing, reflecting increased environmental concerns and increased acceptance of magnesium hydroxide for caustic soda. Animal feed markets are steady, but imports of caustic-calcined magnesia from China are increasingly being barged up the Mississippi River to the major farming states for use in agriculture. This increase in imported material is likely to continue, mainly because of its lower cost compared to U.S.-produced magnesia.

In Europe, the caustic-calcined magnesia market is estimated to be 150 to 200 ktpy, with the majority used for cattle feed. Outbreaks of mad cow disease and hoof and mouth disease in Europe

have had an adverse effect on this market. Animal feed markets are likely to become more difficult to supply with the potential implementation of product certification to prove that there is no contamination of feed ingredients throughout the European Union (EU); this certification is already in place in the Netherlands.

The EU water treatment and flue-gas desulfurization markets have not developed to the extent that they have in North America, and without additional EU legislation that would force a change in practices, these markets are not likely to develop. As with the United States, the EU is facing increased competition from imports of dead-burned magnesia from China. Although the quality is not as high as that of material produced in Europe, the Chinese magnesia can be blended with small quantities of high-purity European material to produce a satisfactory product (Harris 2002).

In Asia, steel production is increasing, and the market for dead-burned magnesia is increasing as well. China's steel production is expanding rapidly, and production in southeast Asia is expected to increase. China supplies its internal needs, and, as with North America and Europe, supplies a significant portion of the Asian market.

Manganese

L.A. Corathers and J.F. Machamer

INTRODUCTION

Manganese (Mn), atomic number 25, is a black, brittle, metallic element. Its most widespread uses are in the steel industry and as a component of dry cells. In the metallurgical industry, manganese is used as a deoxidizing and desulfurizing agent, and as an alloying element in certain steel, copper, and aluminum alloys. Nonmetallurgical applications of manganese include battery cathodes (manganese dioxide), soft ferrites (manganese-zinc ferrites) used in electronics, micronutrients found in fertilizers and animal feed (manganese sulfate and manganous oxide), a water treatment chemical (potassium permanganate), a colorant for bricks and ceramics, and others (see also Weiss 1977; Harben, Raleigh, and Harris 1998).

From antiquity until the latter part of the eighteenth century, the mineral pyrolusite (MnO_2 ; from the Greek words meaning “fire” and “to wash”) was considered an iron mineral. Ancient Egyptians and Romans used pyrolusite to control the color of glass. Adding small amounts of pyrolusite removed the greenish yellow discoloration caused by iron impurities in glass, while further additions colored the glass pink, purple, or black (Wellbeloved, Craven, and Waudby 1990). In 1740, J.H. Pott showed that pyrolusite does not contain iron. In 1774, Swedish chemist and apothecary Carl Wilhelm Scheele recognized manganese as an element, and his fellow countryman, Johan Gottlieb Gahn, isolated manganese metal by reducing manganese dioxide with carbon. Until about that time, manganese was used principally as a colorant in glass and pottery. Manganese ore was first mined in the United States in Virginia and Tennessee in the 1830s apparently for this purpose (Jones 1985).

Specific use of manganese in the steel industry dates from 1839, when the element was shown to improve malleability of ferrous articles. In 1856, Robert Forester Mushet demonstrated that steel could be mass-produced by the Bessemer process if manganese was added (Williams 1981). Not many years later, the bulk manganese ferroalloy industry was established, and, by the 1870s, cheap ferromanganese containing 75% or more manganese was available. Since then, manganese has been essential to the commercial production of almost all steels.

The chemical properties of manganese have been utilized for centuries. Umber, a mixture of manganese and iron oxides, was used as a paint drier by the mid-1600s. By the eighteenth century, the oxidizing power of certain manganese chemicals was recognized. Manganese ores were used extensively to produce chlorine until about 1855.

Manganese use as a significant component of batteries dates from 1866, the year that Georges Leclanché filed the master patent for the zinc-carbon dry cell that bears his name. The Leclanché batteries used natural battery-grade manganese ore (gamma MnO_2). Since the early 1960s, however, the Leclanché battery has been replaced by the alkaline battery, which uses electrolytic manganese dioxide (EMD) as the dominant system in the primary (disposable) battery market. Since the 1970s, manganese also has been used in lithium battery technologies. One of the earliest commercially available and now most widely used primary lithium batteries is the lithium-manganese dioxide battery. Today lithium-ion batteries utilizing lithium manganese oxides also are used in the secondary (rechargeable) battery market.

PRODUCTION AND RESOURCES

Although manganese is the 12th most abundant element in the earth's crust (Parker 1967), minable deposits of manganese ore are uncommon. Excluding China, India, Kazakhstan, and Russia, significant production currently is limited to 13 deposits in seven countries (Table 1). Known manganese reserves are limited to those same countries (Table 2).

GEOLOGY

Geochemistry

In nature, manganese occurs in three valence states: divalent (Mn^{2+}), trivalent (Mn^{3+}), and quadrivalent (Mn^{4+}). Common minerals containing Mn^{2+} include rhodochrosite (MnCO_3), rhodonite (MnSiO_3), alabandite (MnS), and spessartite garnet ($\text{Mn}_3\text{Al}_2(\text{SiO}_4)_3$). (Mineral formulae are from Kretz, Hunt, and Ramsdell 1951; Hurlbut 1959; and Cairncross, Beukes, and Gutzmer 1997.) Mn^{2+} also is common in the carbonate component of many sedimentary rocks in amounts ranging from trace to a few percent. Minerals containing both Mn^{2+} and Mn^{3+} include braunite ($\text{MnMn}_6\text{SiO}_{12}$) and hausmannite (MnMn_2O_4). Minerals with only Mn^{3+} are uncommon and include bixbyite ($(\text{Mn},\text{Fe})_2\text{O}_3$) and manganite ($\text{MnO}(\text{OH})$). Minerals that contain both Mn^{3+} and Mn^{4+} include the many variations within the cryptomelane ($\text{KMnMn}_7\text{O}_{16}$)-psilomelane ($\text{BaMn}_2\text{Mn}_6\text{O}_{16}$) group. Minerals having only Mn^{4+} include the several polymorphs of pyrolusite (MnO_2). Minerals containing only Mn^{2+} , such as rhodochrosite and rhodonite, are frequently very colorful and, thus, readily identified. Otherwise, manganese oxides are brownish-black (hence, braunite)

* Including Ghana.

to black; their luster is dependent on grain size and crystallinity. Manganese ores composed primarily of rhodochrosite tend to be a "dirty gray" color and are distinguished from impure limestones by their high density (heft) and tendency to darken (oxidize) rapidly on exposed surfaces.

Some polymorphs of manganese dioxide are electrochemically active, particularly the gamma form (nsutite), and are important constituents of Leclanché dry cells.

Deposits

Geochemically, manganese resembles iron in that the lower valence forms are highly soluble (mobile) and highly reactive, whereas the higher valence forms are highly insoluble (immobile) and both physically and chemically resistant. Thus, in solution, manganese is transportable in reducing environments and is precipitated and thereby fixed in oxidizing environments. Rocks with significant manganese content tend to develop a manganese crust (called *cuirasse*), which is highly resistant to erosion. They generally form bold outcrops and prominent topographic features. Iron and manga-

nese react similarly in oxidizing environments, but iron oxidizes to its insoluble (ferric) state at much lower oxygen concentrations than manganese does to its insoluble (manganic) state. This difference in respective insolubilities is the principal cause for the separation of the two elements in natural systems (Krauskopf 1957).

Most economic manganese deposits originated as sedimentary rocks with high primary manganese content. With two notable exceptions, these deposits can be grouped into three major types (Machamer 1987). The first group (Type I) is lenticular bodies (actually clusters of lenticular bodies) of bedded rhodochrosite with lesser braunite within belts of early Precambrian (Archean) basic volcanic rocks ("greenstone belts"). Type I deposits are clustered around the South Atlantic Ocean and include Morro da Mina and Serra do Navio in Brazil, Matthews Ridge in Guyana, Grande Lahou in Ivory Coast, N'suta in Ghana, Tambao in Burkina Faso, and Kisenge in Congo. These deposits were or are capped by high-grade supergene manganese oxides; the underlying primary manganese carbonate protore associated with these deposits can also be mined. Some younger manganese deposits can also be of this type, including the San Francisco deposit near Autlan, Estado de Jalisco, Mexico; the occurrences in the Franciscan Complex of California; and those of the Olympic Peninsula of Washington.

With the exception of the undeveloped Tambao deposit and the idle Kisenge deposit, the high-grade supergene ores developed on primary Type I deposits are substantially depleted, as may be the primary carbonate ore at Serra do Navio. Primary carbonate ores are being mined at N'suta, Ghana, and Morro da Mina, Brazil.

The second group (Type II) is composed of distinct and laterally extensive beds of braunite, braunite and manganese-bearing carbonate minerals, or cryptomelane with in some particular and unique, highly oxidized, iron- and silica-rich sedimentary rocks of Proterozoic age. The two prominent examples of Type II deposits are the Hotsel Formation in the Kalahari region of South Africa and the Band'Alta Formation near Corumba, Mato Grosso do Sul, Brazil, and Puerto Suarez, Bolivia. These beds, although not everywhere minable, underlie hundreds of square kilometers and probably constitute the most important manganese resources in the world.

The third group (Type III) is composed of laterally extensive beds of shaly manganese oxides, manganiferous shale, shaly manganiferous carbonate, and/or braunite-rich shale, which were deposited in shelf areas of large epicontinental basins. Prominent examples of Type III deposits are those of the Francevillien Series of Gabon (Bangombe and adjoining plateaus of the Moanda Area); the deposits surrounding the Black Sea (Nikopol', Ukraine; Tchiatura, Georgia; and others); and the Azul deposit associated with the Rio Fresco Series in the Amazon Basin of Brazil.

Among the sedimentary manganese deposits that do not fit an established pattern are the young pisolitic deposits of Groote Eylandt in the Gulf of Carpentaria, Australia, and the unique manganese-rich carbonate bed at the base of the Jurassic Taman Formation in the Molango Area, Estado de Hidalgo, Mexico. Deposits that may be similar to the Molango deposit occur along the eastern slope of the northern Ural Mountains in Siberia (Smirnov 1977). Russia mined the oxidized (enriched) portions of these deposits during World War II. The economic potential of the remaining primary carbonate protore is currently being studied.

The famous deposits of the Mansar Schist Belt in the state of Madhya Pradesh, India (Balaghat, Kandri, Mansar, Tirodi, and others) occur in high-grade metamorphic terrane. The deposits are composed mainly of manganese silicate minerals that were capped by high-grade manganese oxides, which by now have been substantially depleted. These may have been Type III deposits that had undergone a phase of supergene weathering and enrichment before

burial and then were subjected to one or more phases of intense metamorphism.

High-value battery-active ores have been produced from the enriched portions of the following: the Bangombe (Moanda) deposit in Gabon; the N'suta deposit in Ghana; the Morro da Mina and Azul deposits in Brazil; and the Morro da Mina deposits in Mexico. The Imini deposit in Morocco is a bed or beds of friable manganese oxides in a dolomite formation from which ore is obtained for chemicals and ceramics (coloring). In the United States and elsewhere, residual deposits of nodular manganese oxides (derived by the weathering of mangiferous dolomites) were mined for ceramics, where color rather than chemistry was the important factor.

The importance of oxidation and weathering effects on manganese deposits, and the importance of recognizing those effects, cannot be overstated. Weathering effects can extend for a vertical range of at least 100 m deep and, in nearly horizontal beds, can extend inward from the outcrop for several tens of meters. The hard manganese oxide crust, which often develops, makes deposits relatively easy to find and protects them from erosion. Weathering and oxidation can change the mineral composition of the ores, concentrate the manganese, and remove impurities, thus rendering the ore more valuable for certain chemical and metallurgical uses. If weathering results in the development of cryptomelane with a corresponding increase in potash content, or it increases the phosphorus content, the metallurgical value of the ore can be significantly diminished.

Large volumes of manganese nodules occur on the floor of portions of the Pacific Ocean and other oceanic basins. These nodules apparently grow by reduction/solution below the sediment-water interface and oxidation/precipitation above it. In the oxidation/precipitation process, the nodules sequester significant amounts of nickel, copper, and other metals, making the nodules a significant resource of these metals. Recovery and processing of manganese nodules was tested by several consortia in the 1970s, but development was discontinued for technical, economic, and legal reasons.

TECHNOLOGY

Exploration

Prospecting and exploration for terrestrial deposits have relied mostly on interpretation of regional geology, followed by physical examination of selected areas. Deposits that crop out are located readily, but there is no reliable guide to "hidden" deposits. Specialized equipment and vessels are used in exploring for and testing possible development of marine deposits.

Mining and Beneficiation

Metallurgical-grade manganese ore is produced mostly by mechanized operations, but small-scale hand mining and sorting is still practiced in India. Virtually all the larger operations around the world are open-pit mines using standard equipment and methods for overburden removal and ore extraction. Bucket-wheel excavators have been used to remove overburden at the Mamatwan mine in South Africa and in the Nikopol' Basin in Ukraine. Haul trucks and/or conveyors transport this material for further processing. South Africa and Ukraine currently account for the largest proportion of ore extracted from underground mines. Most underground mining commonly is done by room-and-pillar methods. Longwall techniques have been used in Bulgaria, and possibly Ukraine, but overburden pressure made these operations impractical.

Battery- or chemical-grade ores have been produced by selective mining of favorable portions of large deposits mined for metallurgical-grade ore or from relatively small mines operated solely for these specialty ores.

Table 3. Manganese alloy specifications

Alloy	% Mn	% C _(max.)	% Si _(max.)	% P _(max.)	% S _(max.)
Ferromanganese					
Standard					
Grade A	78–82	7.5	1.2	0.35	0.05
Grade B	76–78	7.5	1.2	0.35	0.05
Grade C	74–76	7.5	1.2	0.35	0.05
Medium-carbon					
Grade A	80–85	1.5	1.5	0.30	0.02
Grade B	80–85	1.5	1.0	0.30	0.02
Grade C	80–85	1.5	0.70	0.30	0.02
Grade D	80–85	1.5	0.35	0.30	0.02
Nitrided medium-carbon	75–80	1.5	1.5	0.30	0.02
Low-carbon					
Grade A	85–90	0.75	2.0	0.20	0.02
Grade B	80–85	0.75	5.0–7.0	0.30	0.02
Silicomanganese					
Grade A	65–68	1.5	18.5–21.0	0.20	0.04
Grade B	65–68	2.0	16.0–18.5	0.20	0.04
Grade C	65–68	3.0	12.5–16.0	0.20	0.04
Ferromanganese-silicon	65–68	0.8	28.5–32.0	0.05	0.05

Adapted from ASTM 1998.

Virtually all manganese ores are subjected to some form of beneficiation to achieve greater manganese content and/or to remove undesirable impurities. Beneficiation technology as applied to manganese ores is similar to that for iron ores. Most ores are crushed and screened, with the lump product (+6 mm) generally being smelted and the fine product (–6 mm) used as feed for chemical and/or electrolytic processing. Sink-float (heavy liquid media), jigging, tabling, flotation, and high-intensity magnetic separation are among the methods used to upgrade fine manganese ore. In the late 1990s, Humphrey spirals were used to recover manganese fines from tailings at the N'suta mine in Ghana (Brunner 1999). Pneumatic concentration has been used in Morocco and possibly elsewhere. Some manganese ores, particularly in South Africa and, more recently, Gabon, are sintered to raise the manganese content and recover high-grade fines for metallurgical use.

Physical separation technologies, such as flotation and roasting, and chemical separation processes, such as leaching, have been developed for beneficiating lower grade and more refractory resources, such as those of the United States and the lower grade ores of Ukraine. Generally, these processes are relatively costly and give poor recoveries. Bioleaching also has been proposed for recovering manganese from low-grade ores (Rusin and Ehrlich 1995).

Smelting

Manganese ores for use in the steel industry are smelted to produce three basic alloys: ferromanganese, silicomanganese, and ferromanganese-silicon. Specifications for these alloys are given in Table 3. Ferromanganese can be produced in blast furnaces or in electric-arc furnaces, although blast furnace production of ferromanganese is relatively energy inefficient and has been phased out in many countries. Because manganese losses to slag are relatively high, slag from ferromanganese production is often used as feedstock for silicomanganese production. Manganese alloys, particularly those employed in the production of stainless and other specialty steels, are refined

by blowing the liquid alloy with oxygen in a controlled atmosphere to produce medium-carbon or low-carbon alloys.

Chemical and Electrolytic Processes

Manganese chemicals, synthetic manganese dioxide, and manganese metal are produced by a number of chemical processes. Feedstock for these processes is either manganese carbonate, manganese oxide ore in which the manganese oxide has been reduced to the manganous (divalent) state, or manganiferous slag from the smelting process. The feedstock is leached with sulfuric acid, and the resultant manganese sulfate leachate is either electrolyzed or treated chemically to produce manganese metal (EMM and CMM, respectively), manganese dioxide (EMD and CMD, respectively), manganese sulfate, potassium permanganate, and other manganese chemicals (Dean 1952; Deane 1985; Preisler 1991; Grotheer and Clapper 1993).

PRICES

Manganese ore prices are customarily negotiated between buyers and sellers rather than determined through a central exchange. Price is dependent on a number of factors such as chemical analysis (particularly manganese content) and physical character of the ore. The larger year-to-year users of manganese ore have tended to make their purchases by means of annual contract, rather than by spot market purchases. With the decline in smelting of manganese ferroalloys in the United States, the Japanese have been the key factor in setting annual prices since the early 1990s. After the price to Japanese consumers is set (this is known as the international benchmark price), annual settlements usually follow elsewhere. When required, purchases of manganese ore on the spot market are typically higher than those negotiated by contract.

Because manganese ore prices are normally set via annual contracts between purchasers and sellers, very little information about manganese ore prices is publicly available. *Ryan's Notes* or other industry trade publications usually publish the annual negotiated benchmark prices. The U.S. Geological Survey (USGS) estimates annual U.S. manganese ore prices based on fluctuations in the benchmark prices. *Ryan's Notes* started publishing spot market prices for manganese ore traded in North America, on a dollar-per-metric-ton basis, in January 2005.

SPECIFICATIONS

By far, the great bulk of manganese ore used in the metallurgical industry is to make ferroalloys in the iron and steel industry. Lump ores (+6 mm) are preferred for this use. Metallurgical ores are generally expected to meet the following criteria:

- Contain 45% to 48% manganese
- Have a manganese to iron ratio of at least 8:1
- Contain less than 0.15% phosphorus
- Have trace metals content of no more than a few tens of parts per million
- Have low alumina content

These ores are sold in bulk on the basis of an agreed price per dry metric ton unit (one unit is 1% manganese per dry metric ton). Price can be f.o.b. (free on board vessel at port of loading) or CIF (cost, insurance, and freight unloaded at receiving port), depending on whether the buyer or the seller arranges and pays for shipping and delivery. The purchase agreement will specify the maximum allowable content of fines at the point where the buyer takes possession of the ore. A nominal price per dry metric ton unit was published in industry journals, but such publication appears to have been suspended after 2002.

Manganese ore for use as feedstock for chemical or electrolytic processing will have specifications similar to those for metallurgical ore, except that alumina and phosphorus content may not be as critical as in the metallurgical industry. Because buyers can have different specifications for ore chemistry and mineralogy, some plants are designed to process carbonate ores; others can process oxide ores. As discussed in the section on Prices, the price of ore is usually negotiated on individual bases. Because ore is usually ground prior to digestion, fine ore is preferred to coarse ore.

For use in batteries, feed supplements, or other specialty uses, natural manganese dioxide ore has rigid specifications, the most important of which are minimum content of manganese dioxide and maximum content of trace metals and other impurities. These ores are dried, ground, and bagged at the mine. Ores for ceramics must be uniform and consistent within and between shipments, respectively. Prices for these ores are usually negotiated on individual bases, as discussed in the section on Prices.

HEALTH, REGULATORY, AND ENVIRONMENTAL CONSIDERATIONS

Because there are no known deposits in the United States or Canada that are potentially economic sources of manganese, there is nothing in the regulatory or environmental codes of either country that affect manganese mining operations specifically. Manganese mines in Mexico are not known to be subject to any unusual or site-specific regulation. In Ukraine, manganese mines operate with very high waste-to-ore ratios, and mine land reclamation is important. Australia and Brazil are among the countries where particular attention also is paid to restoration of lands mined for manganese.

Manganese is an essential nutrient, and recommended "adequate intake levels" and "tolerable upper intake levels" have been established (Institute of Medicine 2001). Small quantities of manganese may be added to livestock feed and to fertilizers; however, ingestion of too much manganese or inhalation of excessive manganese dust may have adverse health consequences (Agency for Toxic Substances and Disease Registry 2000).

Some manganese ores can contain relatively high base metal concentrations; one overseas smelter has been investigated as a potential source of mercury emissions.

The widespread and growing use of portable electronic and communications devices that operate on dry cells or rechargeable batteries may lead to restrictions on the disposal of batteries containing manganese. Some imported EMM has been reported to contain relatively high levels of selenium (*Ryan's Notes* 2003).

A complex organic manganese compound (methylcyclopentadienyl manganese tricarbonyl or MMT) has been used in the United States and Canada as an antiknock additive in gasolines, but regulatory authorities differ as to its environmental impact (EPA 1994; Environment Canada 2003).

Strategic Concerns

In the early 20th century, the U.S. government and major steel-producing companies in the United States took steps to ensure that adequate supplies of manganese ore would be available in case of emergencies because of

- The critical role of manganese in steel production
- The past importance of natural battery-active manganese dioxide as a component of dry cells
- No known manganese deposits of commercial importance in the United States and Canada

Steel and ferroalloy companies explored for and acquired manganese deposits and maintained significant equity interests in the

companies established to develop those deposits. Following World War II, the U.S. government, through its Defense Logistics Agency, acquired large stockpiles of manganese ore of various grades, manganese alloys, and other downstream manganese products.

With the end of the Cold War and the economic difficulties in the steel industry in the last two decades, the need to maintain stockpiles and strategic reserves of manganese ore is diminished. To maintain domestic ferromanganese production capability and to reduce its inventories, the Defense Logistics Agency has contracted with one company to convert manganese ore in the stockpile into high-carbon ferromanganese. Other manganese materials deemed in excess of stockpile requirements have been sold gradually. Inventories of manganese materials in Defense Logistics Agency stockpiles at the end of 2002 are given in Table 4. Steel and ferroalloy companies have curtailed exploration for new manganese deposits, and several depleted mines have been closed. The remaining equity interests have been sold so no significant U.S. interests are involved in the international manganese ore business.

OUTLOOK

World steel production has been growing at an average rate of 1% per year for many years, and this rate certainly is expected to increase with the explosive growth in steel production in China and India. Although manganese usage in the steel industry has been increasingly efficient, the net demand for manganese in the steel industry has grown because of the increase in steel production itself (Machamer 2002). Also, the demand for manganese in batteries of all sorts will increase, as will the demand for manganese in other chemicals. All sectors of the manganese industry, therefore, can look forward to continued growth. Manganese ore production capacity, however, has decreased because exploration and development of new mines have not kept pace with the depletion of existing mines. The overall outlook for manganese ore demand is strong, with upward pressure on prices in all sectors of the industry already taking place (Trelut 2004).

Mica

John W. Schlanz and James T. Tanner Jr.

INTRODUCTION

Mica is a mineral that has a rich history of industrial applications. Dating back to as early as 2000 BC, the ancient Hindus believed mica was a mystical medicinal cure. Over the centuries, mica uses have evolved from decorative ornaments, mirrors, stove windows, and shock-resistant materials in early military applications to its more high-tech applications today in construction materials, paper, plastics, paints, electronics, and others.

The term *mica* is derived from the Latin *micare*, meaning to shine or glitter. Today, it is a generic term that applies to a group of aluminosilicate minerals that possess a sheet-like structure. The most common commercial micas are

- Muscovite, a potassium-based mica, usually colorless to pale green
- Phlogopite, a magnesium-based mica that is yellow to dark brown
- Vermiculite, a hydrated biotite found as bronze-yellow flakes
- Lepidolite, a lithium-based mica with a purplish hue

Other micas with less commercial value include zinnwaldite, a lithium/iron-based mica that is gray to brown; biotite, a magnesium/iron-based black mica; and roscoelite, a vanadium/potassium/magnesium mica that can be green or brown.

Muscovite mica enjoys the most diverse market applications, followed by phlogopite and vermiculite. Muscovite and phlogopite possess unique characteristics and are highly valued because of their physical, chemical, electrical, thermal, and mechanical properties. These properties include high dielectric strength, low coefficients of expansion, cold and heat resistance, and high tensile strength, making these minerals excellent raw materials for electrical insulators, reinforcing materials, and high-temperature applications.

Color plays a key role in identifying markets for these two micas: muscovite is lighter and used in more color-sensitive applications. Phlogopite, however, will typically give superior aspect ratios after grinding, adding to its value as a reinforcement additive.

Commercially, mica is marketed in several forms:

- Sheet mica refers to books of mica mined from pegmatite or loosely consolidated clay deposits. The books can be readily split into thin sheets with specific thicknesses ranging from 0.003 to 0.10 mm. The quality of sheet mica is graded according to 10 quality classifications. Flawed books (excess

Table 1. United States production of scrap, flake, and ground mica, 1999–2003, t

Production	1999	2000	2001	2002	2003
Mine	95,000	101,000	98,000	81,000	98,000
Ground products	111,000	112,000	89,000	98,000	107,000
Imports	21,000	29,000	32,000	38,000	14,000
Exports	11,000	10,000	9,000	10,000	7,000

inclusions, cracks, etc.) are termed scrap mica and may find use in ground products.

- Built-up mica was developed in the late 1800s because of the scarcity and cost of sheet mica, and served as a ready substitute for electrical parts. Formed by layering pieces of mica splittings and binding them with inorganic or organic binders, the constituted sheets are pressed under high temperature.
- Reconstituted mica is mica paper matted from thin delaminated flakes of scrap mica. The mat is usually impregnated with an organic binder and dried at 110°C. Feedstock for reconstituted mica is typically trimmings from sheet mica operations.
- Flake mica is finer mica recovered from scrap or trimmings produced during the processing of sheet mica, or can be beneficiated mica recovered from feldspar, clay, and sand operations.
- Ground mica is produced by wet or dry grinding and sizing of scrap or flake mica. It is by far the largest use of mica, both quantitatively and by application.
- Synthetic mica is produced by crystal growth in slowly cooled melts of various chemical oxides. Cooling periods at controlled viscosities dictate the size of the crystals; extended cooling times result in larger crystals.

PRODUCTION AND TRADE

Scrap and Flake Mica

The data given in this section are from the U.S. Geological Survey's (USGS) *Mineral Commodity Summaries 2004* (Hedrick 2004).

The USGS estimates domestic production of scrap and flake mica at 98,000 t in 2003, as shown in Table 1. North Carolina accounted for approximately 40% of this production from four main

mica producers, three of whom recover mica as a by-product from feldspar operations mining pegmatites known as alaskite. This mica is sold to dry-grind producers for the wall board and joint compound markets. The fourth company recovers mica as a primary product from more weathered deposits and produces feldspar, quartz, and kaolin. The company has in-house capabilities for producing both wet- and dry-ground products.

Remaining U.S. production came from five operations in Arizona, Georgia, New Mexico, South Carolina, and South Dakota, primarily from kaolin, feldspar, and sand operations. The majority of all U.S. production served as feedstock for wet- and dry-ground products, with an estimated value of \$20.2 million on flake production in 2003. Value-added ground product sales contributed another \$29.6 million in the same year.

U.S. production of flake mica for 2003 represents a significant increase of more than 20% from 2002, whereas ground products increased at a lesser rate of 9%. However, both figures indicate a near-static industry using the past 5-year average, because 2002 was a down year due to economic conditions. Imports of flake mica were small at an estimated 7% of total domestic consumption, with Canada, India, China, and Argentina listed as leading exporters of flake and scrap mica into the United States.

World production of flake and scrap mica for 2003 is estimated at 300,000 t, with Russia the leader at one third of production (Table 2). The United States fell slightly behind at 98,000 t. World resources of scrap and flake mica are produced from granite, pegmatites, schist, and clay deposits. Reserves are considered more than adequate to meet anticipated world demand for the foreseeable future.

Sheet mica presents an entirely different domestic picture. U.S. production has been virtually nonexistent for many years, with U.S. consumers dependent on imports or shipments from government stockpile excesses, as indicated by the USGS figures summarized in Table 3. A small amount of sheet mica was produced from a pegmatite in Virginia, but is insignificant to worldwide production. U.S. production is prohibitive because of high costs associated with mining and processing, which is labor intensive.

Although demand for sheet mica decreased in 2003 and has dropped dramatically in the last 5 years, high-quality material remains in short supply. In 2003, an estimated 130 t of unworked mica, split block, and mica splittings valued at \$348,000 was consumed by 5 companies in the United States. Most of this tonnage was fabricated into electrical components. An estimated 1,010 t of imported worked mica valued at \$11.1 million was also consumed.

Imports remained a principal source of sheet mica for domestic supply. Stocks of mica remaining in the National Defense Stockpile (NDS) have declined, and future supplies are expected to be increasingly served by imports, primarily from India, which will certainly lead to increased pricing.

India is the leading exporter of sheet mica into the United States, followed by Belgium, China, and Germany. Table 4 contains estimates of major world production and known reserves. No formal evaluation of world resources of sheet mica has been conducted because of the sporadic occurrence of this material. Large deposits are known to exist in Brazil, India, and Madagascar.

Russia, the United States, and Korea were the world leaders in the production of all types of mica through 2002. Table 5 lists world mica production by country from 1998 through 2002.

GEOLOGY AND MINEROLOGY

All micaceous minerals have similar structures and properties and belong to the phyllosilicate class, referring to leaf-like structures characterized by layers of silicon–oxygen tetrahedrons. The mica

Table 2. World production and reserves of flake and scrap mica in 2002 and 2003*

Country	Mine Production, t	
	2002	2003
Brazil	4,000	4,000
Canada	17,000	17,000
India	2,000	2,000
Korea, Republic of	40,000	40,000
Russia	100,000	100,000
United States	81,000	98,000
Others	35,000	35,000
Total	280,000	300,000

* Reserves and reserve base for all listed are considered large.

Table 3. U.S. sources of sheet mica, t

Type	1999	2000	2001	2002	2003
U.S. production	0	0	0	0	0
Imports, plates, sheets, strips, worked mica, split blocks, splittings	4,550	5,430	4,290	1,580	1,140
Exports, plates, sheets, strips, worked mica, crude and rifted into sheet or splittings	1,290	1,150	1,160	723	1,030
U.S. government stockpile excess	708	1,230	1,860	894	1,280
Apparent consumption	3,980	5,500	4,990	1,750	1,390

Table 4. World production and reserves of sheet mica

Country	Mine Production, t		Reserves	Reserve Base
	2002	2003		
India	3,500	3,500	Very large	Very large
Russia	1,500	1,500	Moderate	Moderate
United States	0	0	Very small	Small
Others	200	200	Moderate	Moderate
Total	5,200	5,200	Large	Large

layers are bound by oppositely charged surfaces, with positively charged alkalis linking the negatively charged silicon–oxygen layers. They are easily identified because of their crystal shape, elasticity, and near-perfect basal cleavage; and, because of their molecular structure, they can be readily split into thin films.

Dana (1932), Sinkankas (1964), Bailey (1984), and others classify the various micas into four groups: (1) mica, (2) clintonite (brittle micas), (3) chlorite, and (4) vermiculites. These micas have the following general chemical formula:

where

X = mainly potassium (K), sodium (Na), or calcium (Ca)

Y = mainly aluminum (Al), magnesium (Mg), iron (Fe), or lithium (Li)

Z = mainly silicon (Si) or Al

Given the nature of this writing and its industrial importance, focus is placed on the mica group. Tables 6 and 7 list various properties of selected micas.

Table 5. World mica production by country, t

Mica Group

Elemental substitution takes place within the various micas quite readily. The mica group includes the more common and most widely used mica species such as muscovite, paragonite, and phlogopite. Other micas in this group are biotite and lepidolite. Muscovite and paragonite (both are commonly referred to as muscovite) enjoy the most industrial uses and subsequent exploitation. Muscovite is the most common of all the micas, having a chemical formula $KAl_2(OH)_2(AlSi_3O_{10})$ with a theoretical composition of 11.8% K_2O , 45.2% SiO_2 , 38.5% Al_2O_3 , and 4.5% H_2O . Paragonite is similar in composition, with the potassium replaced by sodium.

Muscovite is commonly found in granites and pegmatites as an original constituent of crystalline rocks high in potash and alumina. Although rare in volcanic rocks, it is commonly associated with mica schists along with biotite. Other host rocks include gneiss, and it is also found in contact zones surrounding igneous

intrusions. The largest and best formed crystals are found in pegmatite dikes associated with granite. Most commercial deposits are derived from pegmatites, both weathered and unweathered, containing 2% to 10% by weight muscovite.

Phlogopite, its name derived from the Greek *phlogopos*, meaning *fire-like*, ranks second in commercial value and is sought for its thermal and reinforcing properties. It has the inherent ability to delaminate easily, resulting in high aspect ratios and low bulk densities. The chemical formula for phlogopite is $KMg_3(OH)_2(AlSi_3O_{10})$, showing substitution of magnesium for aluminum, and having an estimated theoretical composition of 11% K_2O , 43% SiO_2 , 16% Al_2O_3 , and 29% MgO . Phlogopite is associated with ultrabasic rock and metamorphosed limestone and dolomite, and more rarely as a constituent of igneous rocks rich in magnesium. It is a product of both regional and contact metamorphism and is often associated with pyroxene, amphibole, and serpentine.

Biotite constitutes a series with phlogopite, having a similar chemical formula with iron substitution for magnesium. The high iron content, which imparts dark colors, will typically eliminate biotite from any industrial uses. However, because biotite is abundant in granitic rocks, pegmatites, and schists that are also associated with the more desirable muscovites, the mineral is often a factor in exploitation efforts.

Lepidolite is a lithium-based mica with a chemical formula showing substitution of lithium for aluminum— $\text{KLi}_2\text{Al}(\text{OH})_2(\text{AlSi}_3\text{O}_{10})$ —and is not pursued industrially except as a source of lithium. It is confined to granitic pegmatites associated with other lithium-bearing minerals such as tourmaline, beryl, and spodumene. Other lithium-based micas include zinnwaldite, cryophyllite, and manandonite.

Clintonite Group

The clintonite micas are also referred to as the brittle micas, having cleavage similar to the muscovites, but they are distinct in the brittleness of their laminae and chemically by their character. In many respects, they form a transition of the true micas to the chlorites. Examples from the clintonite group include margarite, a calcium-based mica; seyberite, with calcium and magnesium substitution; and chloritoid, which has an iron/calcium base.

Chlorite Group

The chlorite group gets its name from the Greek *chloros* (green) in reference to the common green color associated with these minerals, mainly because of their association with ferrous iron. They are closely related to the true micas in the sense that they exhibit mica-like cleavage, but the laminae are tough and inelastic. Because of the extensive elemental substitution within the series, many names have been applied to a variety of identified species, but for practical purposes, only two are commonly employed. The first, penninite, has thick prismatic crystals and is normally dark green, whereas the second, clinocllore, bears a greater resemblance to true micas, with thin, tubular crystals.

Vermiculites

The vermiculites include numerous micaceous minerals, and in part are closely related to the chlorites, but they vary widely in composition. They are mainly alteration products of the muscovite, biotite, and phlogopite that are highly hydrated. They maintain the micaceous cleavage, but the laminae are generally soft, pliable, and inelastic.

The vermiculites get their commercial value from their high degree of hydration, which gives them the unique quality of exfoliation, or the ability to expand to several times their volume on

exposure to heat and the subsequent evolution of the contained water. Because of this unique quality, the vermiculites service different markets than the micas and are covered in a separate chapter of this book.

THE MICA INDUSTRY

The mica industry can be divided into two distinct but interdependent industries: those that produce sheet mica, and those that produce flake mica. Each industry, although somewhat dependent on the other, produces different end products.

Sheet Mica

The sheet mica industry produces relatively small tonnage as compared to flake—5,200 t versus 300,000 t in 2003 (Hedrick 2004)—which is driven in part by the markets but is also influenced by the high costs of mining and processing sheet mica, the scarcity of these reserves, and the depletion of high-quality material. Because of exacting specifications placed on sheet mica, mining and processing consist of hand cobbing and preparation, resulting in extremely high labor costs. This limits production to countries with cheap labor and, together with low reserves, has greatly influenced U.S. production.

Sheet mica is typically recovered from a large number of small mines that use only basic mechanical equipment, if any. Preparation relies almost exclusively on hand labor to recover the maximum area of usable crystal. Commercial qualities must include flat sheets that are relatively free of defects and flaws, with quality based on complex visual determinations, as indicated in Tables 8 and 9 (a and b). The quality is dictated by size, thickness, visual appearance, electrical and thermal properties, and the degree of preparation.

Commercially, sheet mica is marketed in several forms, depending on the application and quality:

- Block mica, also known as mica block, consists of sorted blocks of mica with an area of 6.5 to 91 cm² (1 in.² to 14 in.²) or greater. The minimum thickness is typically 7 mils; it is available in natural form or split and cut into sizes and shapes specified by the customer. Mica blocks are classified into different categories depending on the extent of staining and other flaws. The average sheet thickness can vary from 7 to 16 mils or greater. Sections having holes, cracks, and cross grains are removed by hand.
- Mica thins consist of block mica dressed to a thickness of 2 to 7 mils. Fabricated mica is made from mica thins for the electrical and other industries.
- Mica films consist of block mica dressed to a thickness of 0.8 to 4 mils and are generally made from high-quality block.
- Mica splittings are layers split from mica blocks and are specified as 10 layers being less than 12 mils thick. Splittings are typically processed by hand with sharp knives to the required thickness. The splittings are classified into three forms: loose-form splittings, book-form splittings, and wrapper splittings. Book-form mica splittings consist of individual books of mica from the same block or mica thins, with each book containing 4 to 10 sheets. Loose mica splittings consist of irregular shapes and sizes that are supplied in a loose form.
- Mica scrap is the irregular pieces of mica from run-of-mine ore that is smaller than the mica blocks with surface areas of 3.25 to 9.75 cm² (½ in.² to 1½ in.²).

Figure 1 depicts a typical process flowsheet for sheet mica. Care must be exercised in the mining process to not damage the sheets while maintaining large surface areas. Therefore, much is

Table 8. Quality of mica based on size (ASTM D351)

Adapted from Mica Manufacturing Co. Pvt. Ltd.

done via hand cobbing after initial blasting (if used). The hand-cobbed books of mica are trimmed and cut manually to remove rough edges and any large flaws or impurities, and sorted by size.

The smaller books report as mica scrap; the larger books are subjected to additional cutting and trimming and classified as mica block. This product may undergo additional hand cutting and trimming before being sorted by size and quality. Quality is determined visually by the workers according to the criteria listed in Table 8, and is therefore highly subjective and dependent on the experience level of the labor force. After classifying the mica block, the workers split the layers by hand and sort them according to thickness into mica thins, mica films, and mica splittings.

Mica scrap is produced from the small books sorted from the run-of-mine ore and may contain the cuttings and trimmings from the mica blocks. The mica scrap is used to manufacture mica paper, or can undergo primary crushing in hammer mills or similar type impact crushers to produce sized mica flake. The mica flake may be used for micanite products or sold to grinding facilities to produce mica powders.

Micanite/Mica Paper

Micanite, or built-up mica, is a sheet product made from thin laminates of mica splittings and, in some cases, mica flake. The pieces of splittings are bonded with various agents such as shellac, epoxies, silicone, or other binders. Variations in the quality of mica and type of bonding agent can impart specific properties to the micanite, producing thick or thin, or stiff or flexible products, which can be manufactured into sheets, ribbons, or other forms.

Mica paper, or reconstituted mica, is similar but is generally produced from flake mica or scrap, and is typically of lower quality. The actual process is similar to making paper: the scrap or flake is pulped with various binders and pressed into paper-like sheets.

Because of sheet mica's unique electrical and thermal properties, most sheet mica products are used in the electronics industries. Its mechanical properties allow cutting, punching, stamping, and machining to exacting tolerances.

Micanite and mica paper, which serve similar markets, are used primarily as electrical insulators. Mica paper is a conventional insulating material and finds many applications for general purposes, but particularly as insulation for bus bars. Both products are used to produce mica tape, an essential insulator for large rotating machines, although the higher grade micanite is desired when greater flexibility is required, such as for end windings of turbine generators and high-voltage cable. Both products may have cloth, glass, plastic, or other backings applied to enhance flexibility.

Other major micanite products are essentially bonding materials, including flexible sheet, heat-resistant sheet, molding mica, and

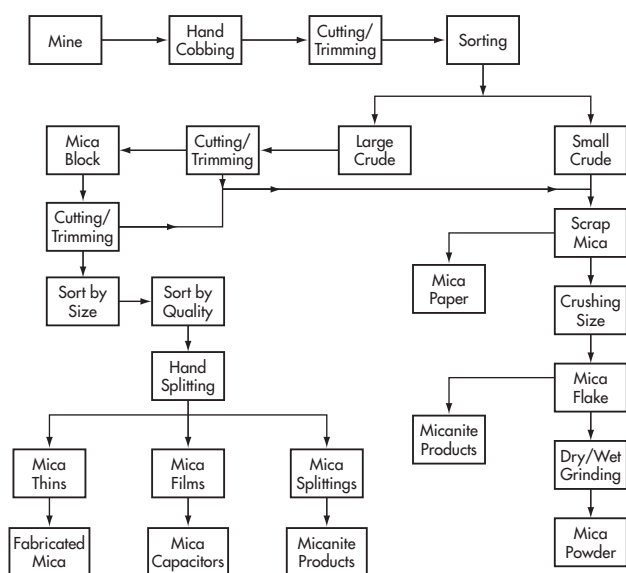

Figure 1. Typical flowsheet for sheet mica

segment plates. Molding mica has found the highest use over the past several years for V-rings, end caps, tubes, and bushings for use as insulators in transformers, armatures, commutators, and motor starters. Washers can be cut or die-stamped from molding sheets for use in electromagnets and control gears.

Flexible sheet, which will typically contain special backings, is used in electrical motor and generator armatures, coil insulation, electric furnaces, and magnet and commutator core insulation. The flexible sheets can be cut to specific sizes and shapes to permit winding or wrapping without heating.

Heat-resistant sheets are used where high-temperature insulation is required and are produced from both muscovite and phlogopite splittings. The phlogopite is used when working temperatures are maximized at 900°C, and muscovite splittings are used below 600°C. Examples of use include electric iron elements, wound heater elements, resistance heaters, and other industrial applications.

Segment plates are prepared by pasting together splittings with a varnish and pressing at high temperature and pressure. These plates, cut or ground to specific shapes, are used as insulators in the copper commutator segments of direct current motors and generators. Phlogopite is the desired raw material because it tends to wear more evenly with the copper elements. Although muscovite is more wear resistant, it may create uneven wear that could affect the operation of the motors.

Table 10 lists estimates of micanite/built-up mica sold or used in the United States by product in 2001 and 2002 (Hedrick 2004).

Fabricated Mica

Owing to excellent natural structural stability and dielectric properties, sheet mica can be fabricated into a wide variety of specific shapes and sizes by hand cutting, stamping, or die-punching. Fabricated mica finds uses in thermionic valve bridges, condenser plates, cathode tube assemblies, optical filters, retardation plates in lasers, and stove and kerosene heater windows. Specialized applications are found in missile systems, medical electronics, and radar systems, and more common applications can be found in domestic uses such as heating elements for irons, toasters, and hair dryers.

Fabricated mica products are typically available in standard shapes and sizes, or can be custom made according to specifications

tions by the manufacturer. Die-punched washers are used in transistors and diodes as insulators to protect against excessive heat. Small discs can be used as spacers in thermionic vacuum tubes, holding the tube elements in position while insulating the elements from each other. Condenser plates are die cut and coated with silver ink for electrodes in mica capacitors.

Lathe-cut discs are used in liquid level indicators, breathing apparatus, communication devices, and fuses. Because of temperature and pressure resistance, thin-cut sheets provide excellent optical mediums for measuring liquid levels and steam pressure in boilers.

Mica Capacitors

Mica capacitors are produced from mica films. The highest quality films are used in the manufacture of capacitors for calibration standards. Lower quality films are used in transmitting capacitors, and the lowest grades go into the production of receiving transmitters.

The films are cut, cleaned, and silvered on each side by a screen-printing process. The thickness of the mica film dictates the capacitance of the plates, and variations in the thickness of the silver coatings control dissipation. The capacitors can consist of single or multiple layers of mica film for stacked units. The stacked units may be interlaced with silver foil, and capacitance is predetermined so the proper number of plates can be used. The plates are generally stamped with multiple patterns and tested for electrical properties. Finished products can be dipped in varnish and treated under heat and pressure to achieve compactness.

Flake Mica

World production of flake mica far out-distances the production of sheet mica (Tables 2 and 4; Hedrick 2004). Although scrap and cuttings from sheet mica production are a source of mica flake, the majority is produced by more conventional means, either from mines operated solely for mica recovery or as a by-product from clay, quartz, and feldspar operations. Some of the mica flake is sold as-is for manufacture of micanite, mica paper, and others, but the majority of flake production is used to produce mica powder via wet and dry grinding.

Flake mica from scrap typically does not need any type of beneficiation, being the result of cautious mining techniques and hand cobbing. Mica flake from scrap can go directly into a product or to grinding mills.

Mica flake recovered from more conventional mining (i.e., by-product from feldspar, mined from pegmatites, etc.) will require some method of extraction from run-of-mine ore. Common methods of extraction, after crushing and grinding, include gravity separation and flotation.

Exploration—Sheet Mica

The spotty occurrence of sheet mica in pegmatites and the unpredictable nature of the size, shape, and attitudes of pegmatites preclude the development of a systematic exploratory drilling program. Drilling can only delineate the pegmatite and will not yield much information about the size, quality, or amount of mica present because sheet mica occurs in and only scattered pockets within the pegmatite, making it difficult to detect its presence and establish any pattern of occurrence. The common method of sheet mica exploration is to sink a test pit in an effort to locate the mica, but this is costly and results are problematic at best. The quality of mica present, however, can be determined with enough certainty to give the miner reason to continue or abort the exploration program. The size, shape, and attitude of the pegmatite are often determined by stripping and trenching. Test pits can be selected in this fashion or information can be obtained to supplement the data from test pits. Another common method of exploring for sheet mica is to sink a shaft along the dip of the vein or sink a vertical shaft to cut the vein at the desired depth. Experienced workers examine any large mica crystals found for quality (Chapman 1983).

Exploration—Flake Mica

Mica ranging from thumbnail to subsize size is found in weathered pegmatites, alaskites, schist (weathered and hard rock), gneiss, and clay deposits. The amount and quality of this mica are evaluated by conventional techniques, usually involving core drilling at 61-m intervals to establish the extent of the deposit. Once the possibility of a viable deposit is determined, a closer drilling pattern is used. In pegmatites, it is necessary to drill on 7.6-m centers to determine the presence of xenoliths or roof pendants, more accurately defining the actual size of the ore body. Drill cores are usually 3.8 to 7.6 cm in diameter and 15 to 31 m long. The cores or drill cuttings are normally removed in 1.5-m segments. Auger drilling is sometimes used in soft material. However, it is very difficult to obtain a representative sample of a particular section when using this procedure because of the probability of intermixing foreign material with the vein material.

Evaluating the cores is difficult and time consuming. Determining the mica content by chemical analysis is of little help because the accessory minerals have the same elements. X-ray diffraction (XRD) can be used but is time consuming and expensive. Petrographic analysis is also time consuming and its accuracy is questionable. A combination of flotation, magnetic separation, and dewatering has been found to be the most effective and least time-consuming method for determining mica content.

Mining—Sheet Mica

Sheet mica is recovered by either sinking a shaft along the strike and dip of a pegmatite or by open-pit surface mining of semihard pegmatite ore. In either case, it is a very economically risky mining procedure because of the cost involved in locating the vein and the unpredictability of the quality and quantity of the mica that might be recovered once the vein is located and worked (Chapman 1983).

In underground mining, the main shaft is driven through the pegmatite at suitable angles to the dip and strike using air drills, hoists, and explosives. Crosscuts and raises are developed to follow promising exposures of mica. When a pocket of mica is found, extreme care is exercised in the removal to minimize damage to the crystals. Small explosive charges of 40% to 60% strength are carefully placed around the pocket and care is exercised with the drilling procedure so the mica will not be penetrated. The charge is just sufficient to shake the mica free from the host rock. After blasting,

the mica is hand-picked and placed in boxes or bags for transporting to the trimming shed where it is graded, split, and cut to various specified sizes for sale.

Sheet mica is no longer mined in the United States because of the high cost of mining, the small market, and the high capital risk. Most sheet mica is mined in India, where labor costs are comparatively low and where there are relatively few environmental regulations.

Mining—Flake Mica

At the present time, flake mica is recovered in the United States from weathered pegmatites, weathered alaskites, weathered mica schist, and unweathered alaskite and pegmatites. Flake mica is also recovered from sedimentary sources associated with kaolin deposits in Georgia (Avant and Pickering 2000). It is mined by conventional open-pit methods. In soft residual material, dozers, shovels, scrapers, and front-end loaders are used in the mining process. Trucks transport the ore to the processing plant. Often kaolin, quartz, and feldspar are recovered along with the mica.

Hard-rock mining of mica-bearing ore requires drilling and blasting. After blasting, the ore is reduced in size with drop balls and loaded on the trucks with shovels for transport to the processing plant, where mica, quartz, and feldspar are extracted.

In earlier times, hydraulic mining was common. Numerous mica washing plants or jigs dotted the sides of the mountains in western North Carolina, Georgia, and Alabama. The soft, weathered mica ore was pushed into a pile with a dozer and washed with hydraulic hoses into the processing plant.

Evaluation and Product Development

As with all industrial minerals, several factors determine the test program implemented in any evaluation project. The material to be tested could be from a new, unexplored deposit or from an existing operation seeking to develop a new market or create a value-added product.

In developing a new or value-added product, much is already known about the material, and the evaluation may be as simple as characterizing the product to determine if it can meet imposed specifications for the targeted market. Some process development may be necessary if the material requires modifications to conform to the specifications.

For an unexplored deposit, the evaluation becomes more complex. Often, not much, if anything, is known about the deposit, and the development could require a multistage project, including several stages of bench testing, followed by pilot-plant testing, and eventually flowsheet design and plant construction.

Bench testing of a previously unexploited ore body begins with a preliminary program in which the feed is characterized and initial beneficiation tests are conducted. Caution must be exercised in obtaining a representative sample for any development program. Mica content and quality should be determined early in the development phase so the process can be designed accordingly (i.e., whether the mica is suitable for wet- or dry-ground products, which will influence the beneficiation approach).

It is never too early to begin investigating markets for any potential products, shipping options, and associated pricing. Good efforts in this area early in the development program can pay tremendous dividends later, particularly in establishing good relationships with possible consumers.

Feed characterization includes chemical analysis, mineralogical examination, and particle-size distribution of either the feed as received or crushed ore, depending on the nature of the deposit. Chemical analysis and mineralogical data allow identification of

the minerals present, leading to identifying potential markets. The size distribution gives an idea to grindability and examining the size fractions will indicate liberation size. The latter is critical; as in most industrial mineral applications, mesh of grind is defined by product specifications and not ore properties, although this is less critical with mica, especially those targeted for wet or dry grinding.

Preliminary beneficiation tests identify the primary product, determine how the material will respond to various processing techniques, give some insight to possible markets, allow the process engineer to become familiar with the material, and manufacture products on a small scale at relatively low cost. In most cases, the focus is to produce the highest grade product possible, and yields are secondary. Obviously, a working knowledge of the markets and pricing, product specifications, and process costs is essential to properly assess resultant data, draw accurate conclusions, and make appropriate recommendations.

Assuming the preliminary testing has been successful (i.e., suitable product can be made, processing is reasonable from a cost standpoint, product yields are acceptable or can be improved, etc.), follow-up bench testing is recommended. The objective of this phase should be optimizing product grades, recoveries, and costs. A small amount of concentrate may be produced and submitted to potential customers for feedback. The possibility of producing secondary products, or by-products, is studied in detail, although an experienced engineer will have a good feel for by-products from the initial testing.

Although the preliminary and follow-up testing can be performed in a single stage, the resultant data should be accurate and complete enough to begin a reasonable economic feasibility study. This should include both operating and capital costs, current product pricing, and other incidentals such as environmental permitting, tailings disposal, and air and water treatment when applicable.

Pilot-plant testing is the next step in the development process. This stage proves the bench process on a continuous basis and provides important scale-up data such as more exact equipment and water requirements (percent solids, retention times, etc.). Process variables can be investigated, allowing the optimization of operating parameters and product grades and recoveries. Tailings and water treatment, becoming ever more important in new operations, can be thoroughly investigated, allowing these treatment circuits to be properly designed.

The pilot plant can produce tonnage of product for the more stringent market evaluations of ten required by the eventual consumers of the product. It is not uncommon for a new raw material to go through a qualification process performed by the consumer. This evaluation can range from the consumer determining key product characteristics in their own laboratory to actually using the product on a trial basis in their manufacturing facility. For the latter, several tons of product may be requested.

Sufficient tonnage for market evaluations is especially critical for industrial minerals and, in particular, mica products. Although market specifications may be defined, performance can often be the determining factor. Producing concentrate for thorough market testing will allow a full evaluation of performance before costly plant design and construction.

The pilot plant can provide an excellent training ground for future operators. In industrial mineral plants, particularly if flotation is involved, variations in the operating parameters can significantly affect product quality. Because product consistency is critical, operators should be aware of the key parameters, how to maintain them, and how to recognize cause-and-effect disruptions so they can be corrected without major loss of production.

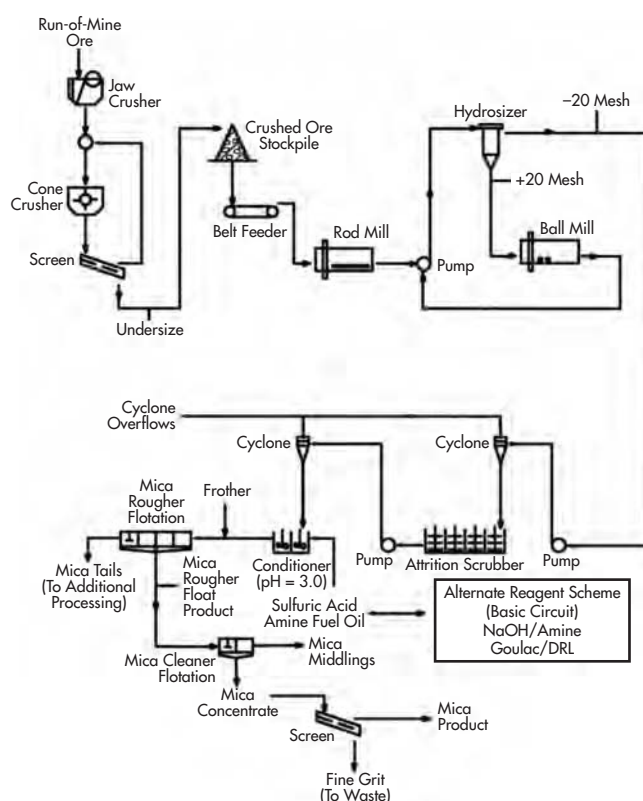

Figure 2. Typical flowsheet for mica flotation

Because finances will be the final justification for proceeding with any development, all bench, pilot-plant, and economic data must be reliable, and a lack of experience or proper information can be fatal to the investors. This again stresses the importance of matching the raw material to proper markets and processes based on product specifications, ore characteristics, and all associated costs.

Figure 2 depicts a common flowsheet for recovering mica from hard alaskite ores and weathered pegmatites via flotation. The run-of-mine ore is subjected to primary crushing using jaw crushers, followed by secondary cone crushing. The cone is typically operated in closed circuit with a screen at 14 mm (½ in.) to ensure a constant feed size to the stockpile. Stockpiling of the crushed ore allows the mine and crushing circuit to operate on an 8-hour day, 5 days per week schedule while maintaining the plant's capability of operating 24 hours per day, 7 days per week.

The 14-mm ore is fed at controlled rates into rod mills for primary grinding. Rod mill discharge reports to screens, or more commonly hydrosizers, to classify the ground slurry at 20 mesh. The oversize, or +20 mesh, reports to secondary grinding in ball mills and returns to the hydrosizer to close down the circuit. The under-size, or -20 mesh, serves as process feed.

Sizer overflow is pumped through cyclones to wash out fines (-200 mesh), which is essential to maintain product specifications on downstream products. The cyclone underflow is thickened and subjected to attrition scrubbing at 65% to 75% solids, preparing the feed for flotation.

Scrubbing serves multiple purposes, including removing surface staining and dispersing any clays or slimes that may be present, and creates fresh particle surfaces for the flotation reagents. Flotation of mica, like most nonmetallic minerals, relies

on the creation of specific surface charges, making surface preparation of the particles via attrition scrubbing essential for efficient performance.

The scrubbed pulp goes through a second cyclone step to remove additional fines and clays freed by scrubbing and to rethicken the pulp for conditioning. Figure 2 shows acid circuit flotation using sulfuric acid to decrease pH to 3.0 or less. An amine-type reagent is used as the primary collector, and #2 fuel oil may be used as an additive. These primary reagents are added to a mixing tank, or conditioner, to ensure complete exposure of the minerals to the reagents.

An alternative reagent scheme allows flotation in basic circuit ($\text{pH} = 7.5$ to 8.0), although it is not as selective as the acid circuit flotation. This reagent schedule requires a second conditioning step and uses caustic soda in the first conditioner as the pH regulator. A highly refined tall oil (DRL) is also added in the first conditioner along with an amine collector. Calcium lignin sulfate (Goulac) is added as a depressant in the second conditioner.

A frother is added to the conditioned pulp on entering the flotation cells. The frother is typically an alcohol-based surfactant that reduces the surface tension between the particles and air bubbles, aiding the attachment efficiency.

Flotation of mica is typically a rougher and cleaner step, with the rougher flotation product (froth product) reporting to a second set of cleaner cells to remove additional gangue minerals. The final cleaner froth product, or mica concentrate, will pass across a fine screen (80 to 100 mesh) to remove any sands that may have been entrapped in the froth. Rougher tailings can be further processed to recover other mineral values.

The screened mica product can be filtered and dried, or simply pumped to drain bins to lower the moisture content. Flake mica recovered via flotation, either acid or basic circuit, is used primarily as feedstock for dry grinding. Although consumers of wet-ground mica prefer products void of any chemical additions, floated flake has been used as feed for wet-ground mica in the absence of sufficient scrap supplies.

Figure 3 shows a typical flowsheet for recovery of mica flake via gravity separation. Spiral separators are the equipment of choice; they take advantage of shape factor and density differences between the mica and sand.

Feed preparation is similar to the flotation process, involving primary and secondary crushing and grinding followed by classifying to a predetermined size (8 to 20 mesh). The ground pulp is pumped to a bank of rougher spirals to produce a preliminary mica concentrate. The rougher product is pumped or gravity fed to a second bank of cleaner spirals to remove additional sands, producing the final mica product. This final product is dewatered in drain bins and used as feed for wet ground or high-quality dry-ground mica powder. The spiral tails may report to flotation processing for the recovery of additional mica and other mineral values.

Spiral concentration offers several advantages to the mica flake producer. No chemicals are used in the process, thus producing a concentrate suitable for wet grinding if the mica properties are compatible. The spirals, using shape and density, also produce a coarser, more delaminated product, leaving the "booky" mica flakes in the tailings for flotation recovery. Recovery of the coarser, highly delaminated flake produces an excellent feed for the grinding process.

A third and less used process for flake recovery is pneumatic concentration. The U.S. Bureau of Mines developed the Zig Zag concentrator using air flow to separate the mica from sands. It contains both a rougher and cleaner zone, each with separate air flows, and the final concentrate is collected from cyclones. Figure 4 presents a conceptual schematic of a Zig Zag installation.

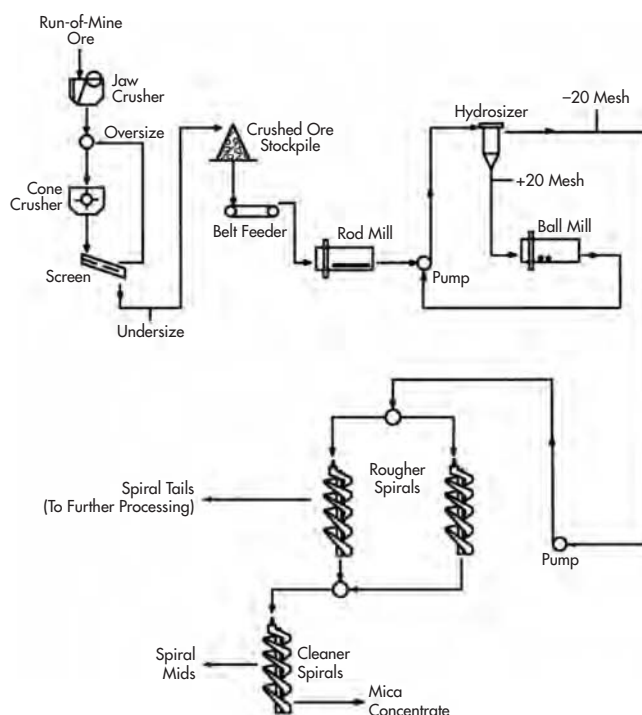

Figure 3. Typical flowsheet for gravity concentration

The Zig Zag separator is essentially an air classifier for coarse particles. The shape and density of the mica as compared to sands allow the mica to act as a smaller particle than equivalently sized sand when introduced into an elutriation type of environment. Therefore, in closely sized fractions of mica-bearing ore, the mica particles will react as a finer particle, thus allowing it to report as an overflow product and the heavier sands drop out as an underflow product.

The Zig Zag concentrator has the advantage of operating dry, thus no water or chemicals are required, and can produce flake suitable for wet grinding if the mica properties are applicable. Because it performs on an elutriation principle, it concentrates mica that already possesses a high degree of delamination at a coarse size, which is advantageous to producing high-grade ground products.

To be effective, the Zig Zag separator requires a feedstock that is relatively high grade, containing coarse mica that is already somewhat delaminated. Any "booky" flake will react as a larger particle and report with the sands, thus limiting recovery. The feedstock must also be classified into narrow size fractions before separation for the elutriation principle to be effective. This requires not only multiple screens but also multiple Zig Zag units to treat the various size fractions.

The United States is one of the world's leading producers of flake mica, using all three beneficiation processes previously described in some capacity. Table 11 shows estimates for U.S. production and value by state for 2001 and 2002 (Hedrick 2002).

Whatever beneficiation process is used to recover the flake mica, it is vital that the mica properties be defined early in the design phase. If the mica is suitable only for dry grinding, then any of the processes can be used. However, if the mica is targeted for wet-grinding applications, using surface-altering chemicals should be avoided and process options should be defined accordingly (i.e., gravity or pneumatic separation). Many operating plants use spiral separation on coarser ore and flotation to recover

finer mica, producing flake for both wet and dry grinding. Table 12 shows a general classification of ground mica by size and use.

Dry-Ground Mica

Dry-ground mica is produced from flake and scrap mica by size reduction in hammer mills and fluid-energy mills. Each produces a size-specific product for different markets. A micronized product, produced in specialized fluid-energy mills, is an extremely fine-sized powder.

Hammer mills produce a relatively coarse product. Mica flake or scrap is fed to the hammer mill, followed by classification. The mill can be run in closed circuit with an air classifier, but screens are used more often because of the coarse product sizes.

A first scalping screen returns coarse mica back to the mill for additional grinding. It is not uncommon for the hammer mill to contain graded sieves to replace the scalping screen, which allows the mica to remain in the mill until it reaches a specific size. The undersize reports to a series of screens to produce sized products for various applications. Figure 5 shows a typical hammer mill setup.

Hammer-milled mica has typical top sizes of 2 to 30 mesh and is suitable for coarser applications such as drilling muds, welding rods, roofing shingles, construction fillers, auto components, and some pearlescent pigment applications. Beneficiated flake mica

Table 12. General classification of ground mica products

Grade	Mesh Size	Typical Use
Coarse flake	6	Oil-well drilling, artificial snow
Medium coarse flake	10	Decorative, Christmas decorations, display materials
Fine to coarse flake	16	Concrete block fillers, refractory brick, gypsum board, asphalt roofing, shingles
Coarse to fine powder	30	Metal annealing, absorbent in explosives, disinfectants
Medium fine powder	60	Welding electrodes, cables and wire, foundry works, pipeline enamel, lubricants, adhesives
Fine powder	100	Textured paints, acoustical plasters, ceiling tiles
Superfine powder	325	Paints, plastics, rubber, paper

Source: Skillen 1992.

Figure 5. Typical hammer mill setup

(flotation concentrates, gravity separated) can also serve some of these markets without requiring additional grinding.

Fine-powdered dry-ground mica and "superfine" micronized mica are produced in fluid-energy mills. These mills use a stream of high-velocity gas to force collision of the mica flakes, resulting in breakage and grinding through particle-to-particle impact and attrition to sizes finer than 100 mesh. Commercial units are equipped with air classifiers to return coarse mica back to the grinding chamber.

Figure 6. Cross-section view of a typical fluid-energy mill

Controlling temperature, composition, and humidity of the gas stream allows other functions to be incorporated into the size-reduction process, including drying. Many dry-ground producers prefer to feed the mica flake at moisture contents of 10% to 15%. Using superheated steam allows for very fine particle size reduction and is used to produce micronized mica. Figure 6 shows a cross-section view of a typical fluid-energy mill for grinding mica flake.

Dry-Ground Products

The largest consumption of dry-ground mica (–100 mesh) is in joint compounds for wallboard. This industry consumed about 59% of U.S. dry-ground products in 2002 (Hedrick 2002). The mica is a cost-effective filler and surface agent in the cement, which fills the joints between panels and is used as a finish coat on ceilings. It acts as a reinforcing pigment that reduces penetration into porous surfaces and enhances the mixing and troweling properties of the compounds. Mica's natural heat resistance, mechanical and thermal strength, and low moisture absorption make it an ideal filler for joint compound applications.

Dry-ground mica's low bulk density and nonabrasive, noncombustible properties make it an excellent filler in gypsum wallboard panels, and an effective replacement for asbestos. It provides good thermal insulation and sound absorption as well as fire resistance—all desirable properties in wallboard panels.

Coarse, hammer-milled mica and beneficiated flake is an additive in drilling muds that prevents loss of circulation and seepage in loose-rock formations. It serves as an effective sealant because of its plate structure, facilitating the overlapping of particles to bridge openings. It also aids in keeping solids in suspension, critical to maintaining or regaining circulation. Various particle-size distributions are used to prevent specific types of circulation loss associated with different rock formations.

About 15% of dry-ground mica is consumed in the paint industry, which is the second largest market (Hedrick 2002). The mica is a pigment extender that enhances suspension, reduces chalking, prevents shrinkage and shearing of the paint film, brightens color tones, and increases resistance to water penetration and weathering. It also increases the paint's adherence to all types of surfaces. Dry-ground products are used extensively in texture and traffic paints where slip and sheen are not as important as in high-quality paints.

High-quality flake (low iron content) is used in pearlescent pigments, providing luster in paints and other decorative products.

It imparts excellent reflective and refractive effects because of its high index of refraction, creating a “mother-of-pearl” appearance that can range from white to silver to a multitude of colors, varying in texture from a silky luster to a glittering sparkle.

In 2002, the plastics industry consumed more than 5% of dry-ground mica production (Hedrick 2002). Mica in plastics serves as an inert filler and extender, especially in automobile parts such as fenders. It acts as a reinforcing material, providing improved mechanical properties and increased strength, stiffness, and dimensional stability while suppressing sound and vibration. Mica-reinforced plastics exhibit reduced warpage and superior surface properties when compared to other fillers and have proved to be effective replacements for more expensive fiberglass in many plastics.

Both hammer-milled powder and ground powder are used in the manufacture of rutile-based welding rods. The mica is added as a flux to prevent slag formation and increase arc stabilization. The mica helps form a fusible slag and produces a good seal at the fusion zone of the arc. It also provides resistance to the harmful effects of oxidation from heat and other gases. The properties contributed by the mica to the flux coating will influence the quality of the welding rod.

Mica is used as an asbestos-free substitute to enhance sound-proofing of acoustical tiles and automobile floors and fire-wall mats. The mica offers multiple advantages in these applications by not only reducing noise but also serving as a vibration absorbent and flame retardant.

The natural properties of mica make it an ideal substitute for asbestos-free friction materials used in applications such as brake shoes and clutch plates. Because mica is not brittle like other inert materials and is stronger than iron, it will reinforce, stiffen, and harden the products, imparting strength to prevent ruptures and reduce warping. Its plate structure allows the mica to lock together under compression in all types of conditions.

Dry-ground mica is used in asphalt roofing shingles and rolled roofing, as a surface coating to prevent sticking of adjacent layers. Dusting the products with mica powder during fabrication improves venting of gases during vulcanization. In a related market, mica is used as a mold lubricant in the manufacture of auto tires. It retains sulfur while permitting air and moisture to escape during curing, creating a uniform pore structure that improves resiliency and reduces shrinkage.

Other uses of dry-ground mica include decorative coatings on wallpaper and UV protection in concrete, stucco, and tile surfaces. It is used in fire extinguishers to keep the powder free-flowing and prevent packing inside the container. When added to certain gaskets, mica powder can reduce shrinkage and increase resistance to swelling from organic liquids and oils.

Wet-Ground Mica

Almost all industrial applications of mica benefit from the grinding process, which enhances its physical properties. These properties improve proportionally to the degree of delamination that occurs. Because wet grinding produces superior delamination as opposed to dry grinding (more breakage), wet-ground products possess significantly better properties and thus higher pricing than dry-ground products. Although economics of wet versus dry grinding can dictate the use of the lower priced dry-ground products, as requirements in composite reinforcement, cosmetics, and paints become more stringent, wet-ground products will become more essential.

The majority of wet-ground mica is produced in chaser-type, or Muller, mills. Although some producers claim proprietary grinding methods that produce good wet-ground products, the Muller mill has proven itself over time to create superb delamination, and

remains a popular choice for wet-ground mica. Figure 7 shows a typical wet-grinding flowsheet using the Muller mill.

Muller milling of mica is a batch process in which the mill is charged with a predetermined tonnage of mica flake. Water is added to the mill to form a paste consistency of 25% to 30% moisture. Grinding periods, which are determined through extensive laboratory tests, can range from 6 to 10 hours. Additional water may be required throughout the grinding period because heat from friction and grinding energy will evaporate the moisture from the batch.

Following the grinding, the mica is flushed from the mill into a sluice box that removes coarse grit or sand. Depending on the mica feed grade, this step may not be required.

The sluice box discharge is pumped to a series of settling tanks to recover the ground mica. Initial settling may last only a few hours, with the overflow reporting to a second settling tank that could have a retention time of up to 24 hours. Underflows are combined and treated for additional dewatering with filter presses or centrifuges. The final overflow is typically lost as waste.

The filter cake, or centrifuged product, is conveyed to a dryer. Indirect heat dryers, such as steam tube dryers, are usually used to minimize losses of fine mica and prevent discoloration. Direct heat dryers, or air-swept dryers, result in excessive losses of the finest product.

The dried mica normally passes through a hammer mill, sand mill, or other type of attritioner to break up any clumps that form during drying. It is then screened to remove coarse mica, which can be returned to the mill for the next grinding period. The screen undersize is packaged for market, or reports to further classification or chemical treatment to produce specific products.

A major challenge in producing wet-ground mica is the dewatering and recovery of the finest mica, which more often than not is the best product. It is not unusual for fine losses to range between 15% and 20% by weight of the final product. Because the use of surfactants and flocculants is avoided to prevent altering the mica's surface properties, much of this fine mica is lost in the settling tank overflows. This has resulted in the use of long settling times.

Wet-Ground Products

Uses of wet-ground mica overlap some dry-ground markets, and include paint, rubber, coatings, plastics, sealants, and so forth. Some exclusive uses of wet-ground mica are in cosmetics, pigments, powder coatings, and wallpaper.

The largest use of wet-ground mica is the paint industry, particularly automotive paints. As a filler in coating formulations, the plate structure of mica adds beneficial rheological properties, reinforcing the paint film during drying and reducing oxidation effects, as well as thermal expansion and contraction. Adding mica to paints also increases flexibility, reduces cracking, and improves adhesion. The mica is compatible with all pigments and is easily wetted with oils, thinners, water, or emulsions, becoming evenly dispersed throughout the paint film. In exterior paints and roof coatings, mica provides UV protection by reducing light penetration, and improves weathering by controlling moisture and gas permeability.

In paints and coatings, wet-ground mica can be used as-is for filler and extender, or can be coated to be a substrate for pigments, creating a variety of special effects from high lusters to pearlescence to two-tone metallic finishes. The high aspect ratios created via the wet-grinding process enhances these special effects.

The ability to highly delaminate produces near-transparent plates that are ideal for the adherence of coatings and light refraction. The mica brightens the tone of colored pigments while transmitting and reflecting light, imparting decorative effects and increasing gloss more effectively than irregularly shaped particles.

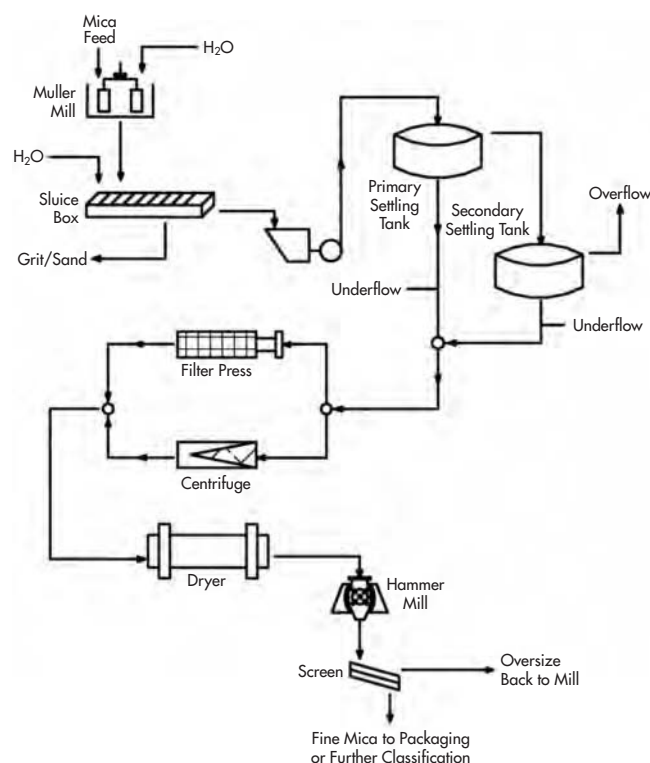

Figure 7. Typical wet-grinding flowsheet using the Muller mill

shaped particles. Controlling the plate thickness can impart different effects. Thin mica plates enhance the pearlescent effects, whereas thicker particles add to luster finishes by creating interference colors and adding depth to the finish.

Coating mica with metal oxides creates nacreous pigments, imparting a high index of refraction that enhances pearlescent or metallic effects. Coating the mica with TiO_2 produces white nacreous pigments. The color effects can be supplemented by overcoating the titanium-coated mica with other colorants such as iron oxide (yellow), ferrocyanide (blue), chromium oxide (green), and carmine (red). Specialty coatings combined with the natural enhancement properties of the wet-ground mica allow for the spectacular colors seen on many of today's automobiles, and also find uses in leather coatings, powder coatings for appliances and outdoor furniture, printing inks, and marine paints.

Mica that is surface modified with silane can improve its performance in paints and plastics. The silane acts as a coupling agent to form a molecular bridge across the organic binders and inorganic fillers of composites to create stronger and more stable bonds. These bonds, which are water and chemical resistant, improve the adhesion properties, prevent moisture penetration for improved durability, and transfer strength from the mica to the resins for better strength and stiffness. Altering the surface from a hydrophilic to hydrophobic state improves dispersion properties, making the mica more compatible with a wider variety of binders and resins.

Wet-ground mica is widely used in the cosmetics industry to produce lipsticks, eyeshadows, nail polish, foundation make-up, soaps, and other bath and body products. Cosmetic grades require Food and Drug Administration (FDA) approval under the *Code of Federal Regulations* (CFR 2002). Because it is inert, nontoxic, and

noncarcinogenic while imparting spectacular decorative effects, it is an ideal additive to skin-care products.

Mica can be added as-is or surface coated, much the same as in paints and plastics. Mica coated with titanium dioxide, iron and zinc oxides, bismuth oxychloride, and other colorants serves as brilliant pigments in cosmetic formulas. Coatings with iron oxide to absorb light, and a further coating of interference color to reflect light creates two-tone effects that appear to change color as the angle of light changes.

Particle size of the mica plays a role in the appearance of cosmetics. Smaller sizes create a smooth sheen, medium-sized particles impart a satin finish, and larger particles give a sparkling effect. The mica's relatively low coefficient of friction improves the spreadability and hiding power, and will disperse readily in most dry formulations.

Mica Powder Quality

Whether ground wet or dry, the quality of mica powders are determined by the following criteria and test procedures:

- Percentage retained on 200 and 325 mesh is measured as follows: with a combination of wet and dry screening, a weighed amount of mica powder is wet screened through a 325-mesh sieve and the +325 mesh is dried and weighed. The residue is placed on a rack of 200- and 325-mesh sieves and ro-tapped for 20 min. The amount of mica retained is weighed and recorded. Results are presented in weight percent retained and cumulative percent passing. The total -325 mesh includes both the wet- and dry-screened fines.
- Bulk density of mica powder is measured using a Scott-White volumeter with a 2.54-cc cube. For coarser micas such as oil-well grades, a 7.6-cc cube, 12.7 cm on a side, is employed.
- True specific gravity is measured with an air comparison pycnometer. Accepted values can also be measured with conventional glass pycnometers using distilled water as the displacement liquid.
- Chemical analysis can be determined by any reliable method, including atomic absorption, x-ray fluorescence, or wet chemistry.
- Free crystalline silica is determined down to 1% using XRD.
- Moisture is determined on a weighed 50-g sample dried at 110°C. After drying, the sample is reweighed and moisture content—reported as weight percent—is calculated from the difference.

$$\% \text{ moisture} = [(\text{wet wt.} - \text{dry wt.}) / \text{wet wt.}] \times 100$$

- The index of refraction is determined using petrographic microscopy and immersion oils of known refractive indices.
- Oil absorption is determined according to ASTM Test D-28 (Gardner rub-out method). A 5-g sample of mica is placed on a smooth glass plate and linseed oil is added drop-wise from a burette with constant mixing with a spatula. When the mica becomes saturated with oil to a point where the mixture begins to curl when the spatula is scraped across the mica, the end point has been reached. The amount of oil is recorded, and results are reported as grams of oil per 100 lb of mica.

$$\text{oil absorption} = (20 \times \text{mm of oil} \times \text{oil specific gravity}) / 45.45$$

- The brightness of the mica is determined by a photovolt reflectance meter (manufactured by the Photovolt Company, a division of Soragen) or other suitable reflectance meters using a green filter (550 μm). The mica powder is prepared by pressing it into a smooth layer, avoiding any cracks or voids.

- The surface area can be measured with any of several surface area analyzers on the market.
- The grit content is an indicator of the amount of “sands” contained in a flake or powder mica product. Although used to evaluate the grade of ground products, it is also used to determine the mica content of beneficiated concentrates.

Grit content of fine mica powder is determined by settling and decantation. A weighed amount of mica (50 g) is mixed in 1 L of water and allowed to settle for 15 sec, followed by decantation of one half of the suspended solids. The mixture is diluted again to a volume of 1 L and is decanted after 15 sec. The procedure is repeated until the decanted slurry begins to become transparent. The procedure proceeds using 10-sec settling times until clear water is decanted. The settled residue, or grit, is collected, dried, weighed, and reported as percent grit. The collected grit may be screened on 70 mesh to report the size of the grit.

Another method uses a Franz Isodynamic separator, which is a high-intensity electromagnet capable of multiple settings. Used primarily on beneficiated concentrates between 16 and 140 mesh, it has proven effective in separating mica, biotite, and sand, allowing an accurate measurement of concentrates grades.

Grit content of coarse micas can be determined by vanning methods. A 25-g sample of mica is placed on a vanning plaque or a 21.6 \times 28 cm piece of rough cardboard. The mica is vanned, allowing the sand to roll away from the mica via shape factors, and the separation is judged visually. Both products are collected and weighed to determine the weight percent of grit.

- The aspect ratio, or the width-to-thickness ratio, can be measured with electron microscope image analysis, although this method is often not reproducible. Laser diffraction techniques are providing more reliable and repeatable measurements.

Table 13 presents estimates on U.S. production of wet- and dry-ground mica powder by use for 2001 and 2002 (Hedrick 2002). Approximate values are included.

The information in Table 13 shows that wet-ground mica enjoys significantly higher pricing in the marketplace compared to dry-ground powders. The 2002 pricing shows wet-ground products selling at an average price of \$960/t, whereas dry-ground averaged \$180/t. Average pricing for 2003 (not shown in Table 13) increased slightly to \$1,000/t for wet-ground mica and \$200/t for dry-ground products. It is also noteworthy that other uses, which accounted for 21% of sales, contributed 44% of the total value. These smaller markets averaged significantly higher unit pricing than all others at \$627/t. Table 14 reports 2002 pricing.

Comparatively, *Industrial Minerals* magazine reports October 2004 pricing as follows (Anon. 2004a; in U.S. dollars):

- Indian micronized—300 to 545/t
- Indian wet ground—500 to 1,000/t
- India dry ground—200 to 430/t
- U.S. dry ground—210 to 400/t
- U.S. wet ground—535 to 1,300/t
- U.S. micronized—535 to 930/t
- U.S. flake—250 to 480/t

Transportation

Mica is shipped by truck or railroad. Maximum truckload shipments are considered to be 20.4 t; maximum rail shipments are 27.2 t. Bulk

truckloads and bulk rail shipments are also made to avoid extra costs for palletizing, bagging, and shrink wrapping. Mica is usually palletized and shrink wrapped for shipment.

Future Trends

Many mica markets are driven by construction, housing starts (wallboard, joint compounds, paints), and consumer durable goods and thus depend on overall economic conditions and a healthy gross national product (GNP). U.S. Census statistics (available at <http://www.census.gov>) indicate an overall increase in housing starts in the United States for 2002, 2003, and 2004, but an increase in U.S. mica production has not been reflected because of foreign imports. Recent natural disasters in the United States in 2004 and 2005 may provide a boost in rebuilding and damage repair.

An informal survey of mica producers and consumers shows an optimism for wet-ground mica because inroads have been made into the plastics and pigments markets, providing a good profit mar-

gin, and a solid market is anticipated for the near future. Less enthusiasm is shown for dry-ground mica because pricing has become stagnant.

An aggressive campaign for U.S. energy independence could result in increased demand for drilling mica related to oil and gas exploration, but this would largely be tied to pending decisions of current political administrations, both domestically and internationally. Off-shore exploration and access to protected wildlife and environmental preserves could increase demand.

Alternative Products

Substitutions for flake and mica powder are not possible in applications that take advantage of the unique properties that the mica imparts to the end product. In certain applications where the mica acts primarily as a filler, some lightweight aggregates such as diatomite, vermiculite, or perlite might be used. Sand and talc have been used as a substitute in roofing shingles because of lower pricing, but the shingle quality suffers. Talc can also be used in place of mica in some lower quality paints as well as mold releases. Boron nitrate, a relatively new cosmetic additive, can replace mica and provide many of the same qualities.

Sheet mica substitutes are numerous, particularly in electrical and insulation uses. These substitute materials include acrylics, cellulose acetate, fiberglass, nylon, phenolics, polyester, styrene, and vulcanized fiber. Trade name products that might be used in place of the sheet mica include Benelex, Delrin, Duranel, Kapton, Kydex, Lexan, Lucite, Mylar, Plexiglass, and Teflon.

GOVERNMENT AND LEGISLATION

Allowance of Deduction for Depletion

The *U.S. Internal Revenue Code* (1997) allows a deduction based on the depletion of natural resources for most mining operations. According to the code, the depletion allowance for mica is quoted at 22% for operations within the United States. The allowance for depletion under Section 611 is applied to the gross income from the property, excluding an amount equal to any royalties paid or incurred by the taxpayer, although such allowances must not exceed 50% of the taxable income from the property computed before the allowance for depletion.

Mining, as defined in Section 613 of the same code, includes not only the extraction of the ores from the ground but also deposits of waste and residue that are reclaimed for mineral values. Also included are the treatment processes and transportation of

the minerals from the point of extraction from the ground to the plants and mills that is not greater than 80.5 km (50 miles). Exceptions for transports greater than 80.5 km can be granted under special circumstances.

Environmental Regulations

Mica mining, like any mining operation, is subject to local, state, and federal regulations. The Mine Safety and Health Administration (MSHA) monitors mica mining operations for conformance to safety standards. Most states have labor departments that mirror the function of MSHA. Both state air and water environmental agencies together with the U.S. Environmental Protection Agency (EPA) oversee air and water quality issues associated with mica mining.

Most states have land management departments that regulate dam safety, erosion, sedimentation, and reclamation. All mines must control erosion and sedimentation and are responsible for restoring mined-out areas. Most reclamation is accomplished through backfilling, contouring, and seeding operations. In cases where this is impractical or undesirable, lakes for water recreation may be built. The U.S. Army Corps of Engineers has jurisdiction over any lands that are designated as wetlands.

Code of Federal Regulations

Mica powders as color additives have been included in the CFR. Section 73.1496 (2002) lists specifications for mica powder as a color additive in drugs. Although exempt from certification, the statute lists limits on particle size at 100% passing 10–60 mesh; loss on ignition (at 600° to 650°C) at less than 2%; lead at less than 20 ppm; arsenic at less than 3 ppm; and mercury at less than 1 ppm.

Section 73.2496 (2002) of the same code addresses cosmetic-grade mica. Although no specifications are listed, cosmetic-grade mica powder as a color additive is approved and exempt from certification. Effective November 26, 2002, Subpart D of the same code (Medical Devices), the FDA amended color additive regulations to provide for the safe use of mica-based pearlescent pigments in contact lenses.

Government Stockpiles

The U.S. government maintains a National Defense Stockpile (NDS) of strategic minerals that includes muscovite block, film, and splittings. The National Defense Act for fiscal year 2003 (Public Law 107-314), enacted into law in December 2002, reauthorized the transfer of funds from the NDS Transaction Fund for operation and maintenance of the NDS.

The bill authorized the disposal of 22,880 kg of all mica types classified as excess to goal. Stocks of mica classified as excess to goal at the end of fiscal year 2002 were not subjected to disposal limits. Excess fiscal year 2002 NDS mica stocks were 10,144 kg of muscovite block, 506 kg of mica film, and 12,230 kg of phlogopite splittings.

Nepheline Syenite

Virginia T. McLemore

INTRODUCTION

Nepheline syenite is a light-colored, medium- to coarse-grained holocrystalline, silica-deficient, feldspathic, plutonic igneous rock largely made up of nepheline, sodium feldspar (albite), and alkali feldspar (orthoclase, microcline), but no quartz. Nepheline syenites are essentially syenites that are undersaturated in silica. Crystallizing from magma undersaturated in silica results in the formation of nepheline instead of albite feldspar (Harben 2002). Trace minerals include sodalite, augite, aegirine, biotite, hornblende, sphene, zircon, iron oxides (magnetite), apatite, garnet, muscovite, corundum, and other minerals rich in alkalis or in rare earth elements (REEs). Commercial nepheline syenites typically are high in alumina (>23%), low in silica (<60%), low in iron (<2% Fe₂O₃), and high in alkalis (Na₂O + K₂O >15%).

As a raw material, nepheline syenite is used in manufacturing glass, ceramics, and flatware (Allen and Charsley 1968; O'Driscoll

1990; Potter 1990; Bourne 1994; Guillet 1994). The major commercial deposits for glass and ceramics use are in Ontario, Canada, and North Cape, Norway (Tables 1 and 2; Figure 1). The largest production of nepheline syenite, however, is from four operations in Russia for manufacture of alumina with by-products of sodium, potassium, and portland cement (Table 3). Russian deposits are generally too high in iron for use in glass and ceramics. Deposits elsewhere in the world have been mined for predominantly local use (Tables 1 and 2; Figure 1), but little information is available about these operations.

Phonolite, the fine-grained equivalent of nepheline syenite, has been exploited in France, Germany, and the Czech Republic (Bolger 1995). Because of its fine grain size, however, phonolite is difficult to upgrade to a high commercial standard. Material containing 2% to 5% Fe₂O₃ can be used in the manufacture of colored glass and some ceramics.

Australia	Nepheline syenite	None
Cameroon	Nepheline syenite	None
Congo	Nepheline syenite	None
Angola	Nepheline syenite	None

Adapted from Woolley 1987; *Industrial Minerals* 2003.

Nepheline syenite is used in products other than glass and ceramics. Its high-strength and weather-resistant properties allow for uses as roofing granules, road materials, rip rap, as well as asphalt and concrete aggregate (Allen and Charsley 1968; McLemore and Guilinger 1993, 1996; Guillet 1994; McLemore, Guilinger, and Oumiette 1994; McLemore et al. 1996a). Because nepheline syenite has high brightness, inertness, and easy wetting and dispersion in parent formulations, it is desired in pigments and fillers. Its UV attenuation characteristics and resistance to weathering make it suitable for use as roofing granules by blocking sunlight and preventing degradation of an asphalt roof. Fines are used as a coloring and fluxing agent in the manufacture of brick and as compaction fill. For local needs, nepheline syenite is used as dimension and crushed stone. Its lack of quartz, or free silica, and relative hardness enables nepheline syenite to be used as a silica-free abrasive. Other potential uses include as fertilizer, ingredients in refractory cement, and paper (Allen and Charsley 1968).

PRODUCTION AND TRADE, RESOURCES, AND RESERVES

Nepheline syenites are found throughout the world (Figure 1, Tables 1, 2, and 3; Allen and Charsley 1968; Woolley 1987; Platt 1996), but only a few deposits are sufficiently low in iron, or have iron in a form that could be inexpensively removed, for use in glass or ceramic manufacture. Magnetic separation, however, after drying and crushing can reduce the dark iron-mineral content. Production of nepheline syenite for glass and ceramic use is mostly from mines

at Blue Mountain, Havelock, and Nepton, Ontario; and North Cape, Norway, where resources are adequate to meet future needs (Table 1). The world's largest nepheline syenite deposit is on the Kola Peninsula in Russia and is mined for alumina. Other deposits in the world, some of which have had test shipments or minor local production, have been explored (Tables 1 and 2), but no known significant production has occurred, except for uses other than glass and ceramics. Other uses are typically included in aggregate production, and separate figures are not readily available. Because commercial nepheline syenite is a high-bulk, low-cost material, it typically needs to be located near appropriate transportation and within reasonable distance of potential markets.

GEOLOGY Mineralogy

In North America, typical nepheline syenite consists of approximately 25% nepheline, 55% sodium feldspar (albite), and 20% potassium feldspar (microcline). In Norway, typical nepheline syenite consists of 34% nepheline, 56% potassium feldspar, and 10% biotite and pyroxenes. The most common of the feldspathoid minerals, nepheline is nominally a sodium aluminosilicate with the formula $\text{NaAlSi}_3\text{O}_8$, but potassium invariably substitutes for a portion of the sodium. The amount of potassium (K_2O) in natural nepheline ranges from 2.5% to 10% (3% to 12% K_2O) by weight. In an alkali-rich magma deficient in silica, nepheline will crystallize, instead of albite and quartz. Accessory or trace iron minerals

Figure 1. Nepheline syenite mines and deposits worldwide

such as corundum, zircon, or other refractory minerals are undesirable. Other feldspathoid minerals in nepheline syenite include leucite, sodalite, and crancrinite.

Chemical Properties

Like feldspar, nepheline syenite provides alkalis that act as a flux to lower the melting temperature of a glass or ceramic mixture, which prompts faster melting and saves fuel (Allen and Charsley 1968; O'Driscoll 1990; Potter 1990; Bourne 1994; Guillet 1994). It also improves the workability of the glass batch by lowering the viscosity, and it imparts a unique quality of toughness to the glass, which makes it more resistant to breakage. The alumina in nepheline syenite increases resistance to scratching and breaking, improves thermal endurance, and increases chemical durability. The low iron content provides the necessary whiteness of the powdered material utilized for clear glass and other end uses, such as fiberglass, extender pigments, and fillers.

Nepheline syenite has a higher alumina/alkali ratio (37%, compared to 30% in sodium feldspar and 32% in potassium feldspar), which means less material is required to achieve the same fluxing action (Saller 1999). With rising temperature, the alkalis become more active and first dissolve the clay particles and then the free silica (Saller 1999).

Minor amounts of iron are observed in the alkali feldspars within nepheline syenite (Platt 1996). Iron concentrations are frequently higher in sanadine than in orthoclase and microcline, which typically contain <0.2% Fe. The iron content is related to magma temperature.

Structure

Nepheline belongs to the hexagonal crystal system, and the structure is based on six-member rings of silica tetrahedra, with apices alternating in direction, forming hexagonal and polygonal voids. Al^{3+} replaces Si^{4+} in some of the tetrahedra and therefore compensates

types of economic deposits. Economic nepheline syenite deposits for glass and ceramic use, however, are rare because few are low enough in iron content and refractories. In addition, these deposits are not typically found in the vicinity of other types of economic deposits. Nepheline syenite from the Khibiny Complex on the Kola Peninsula in Russia is recovered for the manufacture of aluminum, a by-product of apatite production. Some nepheline syenite deposits that are potentially suitable for glass and ceramic use are not currently economic because they are too far from potential markets or the available transportation facilities are inadequate. The major deposits that have produced or are producing nepheline syenite are listed in Table 1; other deposits are listed in Table 2, many of which have had minor production. Many additional deposits are found in the world (Allen and Charsley 1968; Woolley 1987), but they are remote from markets or little information is available at the current time.

Major Deposits

Russia

In Russia, Apatit Production Association produces apatite and nepheline syenite from the Khibiny Complex, the world's largest phosphate deposit and the largest agpaite nepheline syenite complex. Annual capacity is 1,500,000 t of nepheline syenite (Levine and Wallace 2000). The unique apatite–nepheline deposits of the Khibiny Complex, discovered in 1924 and mined since 1929, are a major source of very high-grade phosphate, aluminum, and Portland cement using nepheline concentrates from the apatite tailings.

The 362- to 377-Ma domed complex is approximately 40 km in diameter (Figure 3; Kramm et al. 1993) and composed of several intrusive phases emplaced in the following succession: (1) alkaline-ultrabasic rocks, represented by relics of ultrabasic rocks and early ijolite; (2) large intrusions of agpaite nepheline syenite (also known as khibinites) in the outer arc and the core; (3) late ijolite and urtite; and (4) carbonate stock. Apatite–nepheline deposits are associated with the ijolite–urtite that forms an arc approximately 100 m thick and 11 km long within the agpaite nepheline syenite (Guillet 1994; Dudkin and Tyapina 1997). The deposits consist of 10% to 80% nepheline; 15% to 75% apatite; 1% to 25% aegirine;

and 5% to 12% sphene, titanomagnetite, and feldspar (Notholt 1979; see Table 5 for a chemical analysis of nepheline syenite from various areas of the world).

Mining operations consist of four facilities, an apatite–nepheline beneficiation complex consisting of two plants, and auxiliary facilities. The Apatit Production Association has explored deposits of apatite–nepheline ore, with total ore reserves of more than 3.6 billion t. The deposits are developed by two open-pit and three underground mines at Yukspor, Kirovsk Saami, Rudnik Rasvumchorr, and Tsentralny (Figure 3). Production from two additional

Figure 4. Geologic map of the Blue Mountain nepheline syenite deposit, Ontario

open pits, Koashva and Nyorkpakh, has occurred in the past. Pilot tests to produce titanium–silicon pigment from sphene concentrate have been successful (Dudkin and Tyapina 1997).

Nepheline syenite is a by-product of REEs production from the Lovozero massif on the Kola Peninsula. The massif, 351 to 371 Ma, is a layered suite consisting of eudialytic syenite and alternating layers of foyaitite, urtite, luja vrite, and associated rocks (Vlasov, Kuz'menko, and Yes'kova 1966; Kramm et al. 1993). Loparite is the predominant REE mineral mined.

At Kiya-Shaltyr and Goryachegorsk mines in Siberia, nepheline is recovered from urtites and ijolites and used for produc-

ing alumina (Levine and Wallace 2000; Kuzbass Chamber of Commerce and Industry 2002).

Ontario

Blue Mountain, Havelock, and Nephton in Ontario are the largest nepheline syenite deposits for glass and ceramics industries in the western hemisphere. Approximately 58 km northeast of Peterborough in Methuen Township, they are reachable by both highway and railroad and are probably the first operations mined for nepheline syenite in North America, with production beginning in 1935. When Unimin Corporation purchased the deposit from Indusmin Division of Falconbridge Ltd. in 1990, it became the world's largest supplier of nepheline syenite and feldspar. Reserves are estimated at 19 Mt with large resources available for future exploration (Dawson 1961; Turek and MacGregor 1984).

The Blue Mountain and Nephton nepheline syenites are part of an 1,280-km belt of nepheline syenite gneisses in the Grenville Province of southern Ontario. The origins of this belt are controversial, with theories ranging from primary alkaline igneous origin to metamorphic to metasomatism (Payne 1968; Currie 1976).

The Blue Mountain nepheline syenite gneiss, 1,285 Ma, is a very homogeneous body forming a teardrop-shaped mass approximately 2,130 m long and 1,000 m wide (Figure 4) (Krough and Hurley 1968). Epidote-amphibolite-grade metasedimentary rocks surround the deposit. The nepheline syenite is zoned with a core of hornblende nepheline syenite surrounded by biotite nepheline syenite and marginal outer zones of nepheline-poor muscovite syenite. Typically, the nepheline syenite is foliated to massive, coarse- to medium-grained white rock with a granitic texture that consists of albite (50% to 54%), microcline (20%), nepheline (22% to 30%), 4% mafic minerals, and other accessory minerals, including aegirine-augite, andradite, biotite, calcite, cancrinite, corundum, hastingsite, hornblende, magnetite, muscovite, riebeckite, and zircon. Because of its homogeneity, medium- to coarse-grain size, and low iron content, the deposit is economic (Table 6).

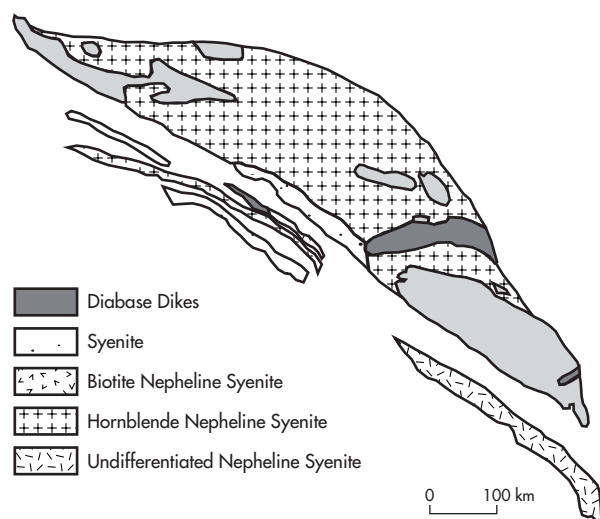

Norway

At North Cape, Stjernoya, Norway, 10 Mt of nepheline syenite have been produced on Stjernoya Island since 1961 when Norsk Nefelin,

Figure 5. Geologic map of the North Cape nepheline syenite, Stjernoya, Norway

a division of Elk em-Spigerveket AS, began mining underground (Geis 1979) on Stjernoya Island. A series of mergers and acquisitions resulted in Unimin Corporation acquiring the property in 1993 from North Cape Minerals Co. (which had bought it from Norsk Nefelin). Even though Stjernoya is 400 km above the Arctic Circle, the warm waters of the Atlantic Gulf Stream keeps the ports free of ice all year. The nepheline syenite is used in glass and ceramics.

The deposit is lens shaped, 1,700 m by 300 m in size (Figure 5), and consists of weakly foliated biotite- and hornblende-pyroxene-nepheline syenites, which contain feldspar (56%); nepheline and minor plagioclase (34%); hornblende (0.3% to 2.5%); biotite (2.5% to 6%); aegirine (1.3% to 3.8%); calcite, clinopyroxene, titanite (trace to 1.2%); and magnetite (Geis 1979). Associated rocks include alkaline pyroxenites, carbonatites, and fenites. Chemical analyses are given in Table 7. Reserves exceed 300 Mt (Geis 1979).

Other Deposits in North America

French River, Ontario. Also known as Bigwood-Rutter or Bigwood, this deposit lies near the northeast corner of Georgian Bay straddling the French River and consists of nepheline syenite gneiss within an alkaline syenite complex that is 975 Ma (Hewitt 1961). The more northerly Rutter nepheline syenite is coarse to medium grained, granoblastic, moderately foliated to massive and consists of salmon pink nepheline (12% to 49%); white albite (16% to 40%); pink microcline (6% to 22%); perthite (3% to 56%); and hastingsite (1% to 24%); with aegirine-augite, apatite, biotite, titanite, zircon, magnetite, and opaque minerals. Approximately 5,000 m by 500 m in size, it contains numerous small pegmatitic segregations.

The southern French River nepheline syenite is similar but contains only 12% to 25% nepheline; 40% white albite; 30% white microcline; 10% biotite; and less hastingsite, with minor graphite, zircon, pyrite, and magnetite (Hewitt 1961). It is approximately 4,000 m by 700 m in size and strongly foliated. Syenite completely surrounds both nepheline syenites. Chemical analyses are given in Table 8. The nepheline syenite is intruded by pegmatites containing sodalite, cancrinite, and molybdenite.

When Steep Rock Resources Inc. examined the deposits during 1980 to 1984, it found flotation methods to be most effective in

removing the iron minerals. Since 1991, SGS Lakefield Research has tested some of the material.

York River, Ontario. Nepheline gneiss was quarried in several areas for ceramic or aluminum use, but the high calcium probably makes it undesirable for ceramic manufacture (Currie 1976). The 903-Ma gneisses form thin east-dipping sheets in between granitic and gabbroic rocks. The upper portion of the layered bodies is leucocratic. Table 5 gives chemical analyses.

East Road, Ontario. East of Bancroft, this deposit consists of two broad bands of nepheline gneiss within hybrid syenite. The 900-Ma nepheline gneiss contains nepheline, plagioclase, biotite, and corundum, and a scapolite nepheline gneiss is present (Currie 1976). Nepheline-bearing pegmatites with minor biotite,

hornblende, calcite, garnet, zircon, galena, apatite, and molybdenite were prospected for nepheline and corundum. No economic development has occurred.

Coldwell Complex, Ontario. About 375 km northeast of Sault Ste. Marie near Lake Superior, this deposit is 25 km in diameter and was examined for nepheline (Woolley 1987). The rock types that make up this complex are 1,108 Ma and consist of gabbro, ferroaugite syenite, syenite to syenodiorite, biotite gabbro, nepheline syenite, granite and quartz syenite, as well as hybrid syenites (Shaw 1997). The complex consists of three overlapping ring complexes that become progressively younger to the southwest. The nepheline-bearing rocks, including nepheline syenite, form a ring in the western part of the complex and vary in texture from allotropic granular to porphyroclastic to mosaic granoblastic (Mitchell and Platt 1982).

Ice River, British Columbia. An alkaline ultramafic complex approximately 23 km south of Field, this deposit is located near and in the Yoho and Kootenay national parks. This deposit was originally closed to mineral prospecting because of its location, but recent "right to access" legislation introduced in British Columbia

has redefined the area as "Special Management," and, with careful planning, economic development within property boundaries is allowed (Currie 1976; Termuende and Geo 1998).

In the 18-km-long U-shaped Ice River complex, two distinct suites are present: (1) an early, rhythmically layered, jacupirangite (feldspar free), ijolite, and urtite, cored by a carbonatite plug and crosscut by carbonatite dikes rich in mafic silicates and oxides; and (2) a later zoned and crosscutting syenitic series, associated with a zeolite and feldspar-bearing carbonatite. Graded layers are 10 to 200 m thick and nepheline increases toward the top of each layer and with differentiation, except for the last carbonatite intrusion (Currie 1976; Termuende and Geo 1998). Ijolites predominate and consist of clinopyroxene, nepheline, phlogopite, magnetite, and sphene. Urtites are coarse grained, foliated, and consist of nepheline with lesser aegirine and minor amounts of wollastonite, kaersutite, melanite, albite, sphene, calcite, and apatite.

A thin rim of saturated fine-grained leucosyenite in contact with the country rocks surrounds the complex. The syenites are unlayered, forming an elliptical pipe-like mass, zoned from a greenish sodalite syenite core through pale gray nepheline syenite to darker-colored mafic-rich rocks at the margin. Chemical compositions are in Table 9. Approximately 43 Mt of nepheline syenite have been delineated (Termuende and Geo 1998). The area has potential for magnetite, lead-zinc, and sodalite.

Trident Mountain, British Columbia. About 83 km north of Revelstoke in the Big Bend of the Columbia River, a lenticular nepheline syenite gneiss forms the core of the mountain range and contains nepheline (10% to 40%); white to pink microcline (25% to 50%); white albite (10% to 30%); biotite (trace to 30%); and aegirine (Currie 1976).

Mount Copeland, British Columbia. On the southeast flank of Frenchman's Cap Dome, 25 km north west of Revelstoke, three main alkaline rocks are exposed: a basal nepheline syenite gneiss overlain by alkaline amphibolites and syenites. The nepheline syenite is zoned and consists of nepheline, K-feldspar, and albite with minor aegirine and sphene. A chemical analysis is in Table 5.

Obedjiwan, Quebec. On the north shore of the Gou in Reservation, approximately 150 km north of Chibougamau, this deposit is 8 km in diameter and is zoned from a core of nepheline syenite to aegirine syenite to a rim of gabbro (Currie 1976). The central nepheline syenite is 1,050 Ma, lineated to foliated, coarse-grained, and consists of albite, microcline, perthite, nepheline, and biotite. An ijolite plug, 199 m in diameter, lies within the nepheline syenite. Although the area is remote, preliminary tests were made to recover nepheline and nepheline syenite, but the results of the tests are unknown. A chemical analysis is given in Table 5.

Fourche Mountain, Arkansas. Since 1947, Fourche Mountain nepheline syenite, in Pulaski County, has been quarried and crushed for use as roofing granules, road material, riprap, and asphalt and concrete aggregate by 3M Co. Fines are used as a coloring and fluxing agent in the manufacture of bricks and as compaction fill. Impurities within feldspars are too fine to remove for use in glass and ceramics. Bauxite derived from weathering of the nepheline syenite was first mined in 1895 for alumina. Two types of syenite, a blue nepheline syenite with hornblende and a gray biotite nepheline syenite, are found. Chemical analyses are in Table 10. Other nepheline syenites are found in Hot Spring and Saline counties, Arkansas.

Wind Mountain, New Mexico. This is one of several plutons that form the Cornudas Mountains in the northern Cenozoic Trans-Pecos alkaline magmatic province. With an approximate diameter of 2.5 km, Wind Mountain is one of the largest exposed intrusions in this belt (McLemore et al. 1996a, 1996b). There has been no production

except for test shipments in 1995 of nepheline syenite for use as sand-blasting material.

From 1991 to 1995, Addwest Minerals, Inc., began exploration and development of the Wind Mountain nepheline syenite for use in manufacturing amber-colored beverage containers, flatware, and ceramics for use as an abrasive and as roofing granules (McLemore et al. 1996a). The company is presently for sale, and the future of mining at Wind Mountain is unknown.

The Wind Mountain laccolith consists of six mineralogical and textural zones (Table 11; Figure 6; McLemore and Guilinger 1996; McLemore et al. 1996a, 1996b). The laccolith is typically gray to cream colored and weathers to darker colors. Accessory minerals form dark-colored aggregates dispersed throughout the rock. Chemical variations among the individual map units within the laccolith cannot be readily discerned by utilizing major element analyses (McLemore et al. 1996a, 1996b). The syenites, however, contain more barium and strontium than do the nepheline syenites (McLemore et al. 1996a, 1996b). These chemical analyses of the Wind Mountain laccolith suggest that the zonation appears to be controlled by crystal fractionation, volatile separation, and cooling history, not different pulses of magma (McLemore et al. 1996b). Differential cooling of the magma resulted in the textural variations at Wind Mountain.

The outer zone of the Wind Mountain nepheline syenite (TNSP₂) was developed as a constituent in glass, ceramics, and flatware, and for use as an abrasive. Compared to other commercial sources of nepheline syenite, the Wind Mountain nepheline syenite contains high iron (Table 11). When the Wind Mountain nepheline syenite is crushed and passed through a specialized rare-earth magnet, however, the resulting product is similar in composition to a Grade B product specified by Unimin Canada Ltd. and has been certified by Coors Inc. as being suitable for amber-colored glass and ceramics. Physical and chemical test results of Wind Mountain nepheline syenite meet or exceed standards for use as roofing granules, dimension stone, aggregate, and abrasives (McLemore and Guilinger 1996).

Mining is projected to be by underground, room-and-pillar methods, and planned processing methods are crushing, grinding, magnetic separation, and screening. At full production, Wind

Mountain is expected to process 3,000 tpd or 700,000 tpy. Current proven, probable, and inferred reserves total 200 Mt for a mine life of more than 100 years (*Industrial Minerals* 1995).

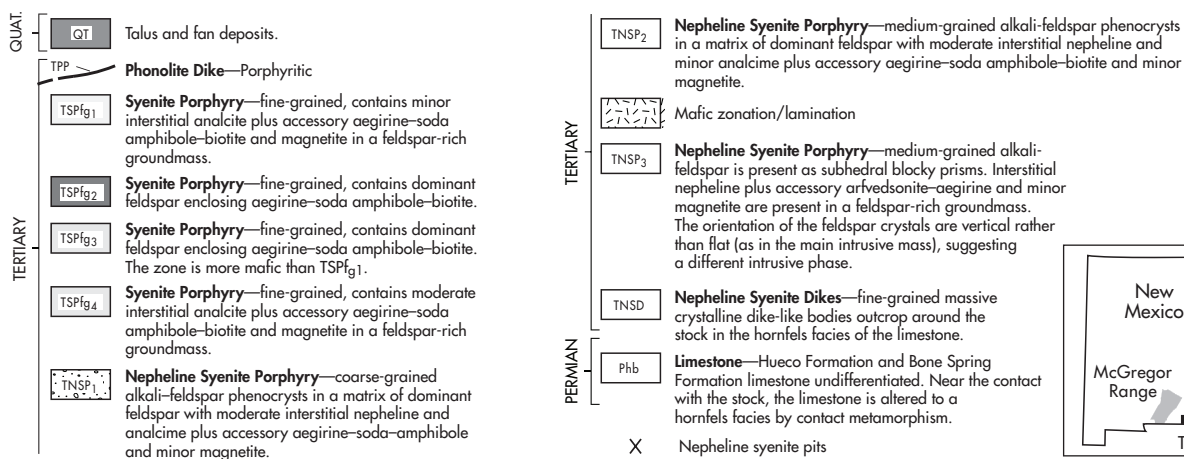

Additional mineral resource potential in the Cornudas Mountains is limited. Although the nepheline syenite of nearby Deer and San Antonio mountains may have potential for glass or ceramic use, the other laccoliths, dikes, plugs, and sills are not suitable for glass or ceramic use because of high iron contents and heterogeneous composition (Table 11).

Table Mountain, Oregon. Located in Lincoln County, this deposit is approximately 1 km² and 100 m thick and contains an estimated 700 Mt of nepheline syenite of 33.6 Ma. Light to medium gray (with a blue tint), it takes a good polish and contains nepheline, albite, analcime, aegirine-augite, olivine, riebeckite, and opaque minerals (Tatsumoto and Snavely 1969).

Other Deposits in the Rest of the World

Canaán, Brazil. About 40 km from the city of Rio de Janeiro is a 20-km² circular litchfieldite stock that intruded Precambrian quartzofeldspathic gneisses and migmatites and is surrounded by alkali syenite. The litchfieldite contains 55% microcline and perthite, 20% nepheline, 15% albite, and 10% biotite, and minor amounts of cancrinite, sodalite, corundum, zircon, pyrite, magnetite, and accessory minerals (Woolley 1987; Guillet 1994). Chemical analyses are in Table 12. In 1978, Austral Mineracao and Servicos Ltd. tested nepheline syenite in a pilot plant, but it did not go into production even though nearby markets were identified. Companhia Baiana de Pesquisa Mineral (CBPM) developed the deposit, which consists of 8.4 Mt of reserves that have to be magnetically separated, and then sold it to Unimin Corporation for production.

Gardar Alkaline Province, Greenland. This contains three nepheline syenite complexes: Ilimaussaq, 1,130 Ma (Paslick et al. 1993), Gronnedal-Ika, 1,300 Ma (Blaxland et al. 1978), and Igaliq bodies. Currently, mining companies are examining the potential for REEs, U, Zr, Y, and Nb (Steenfelt 1991). Ilimaussaq is an oval complex that shows an extensive fractionation trend from alkaline augite syenite to peralkaline agpaitic nepheline syenites (Markl 2001). Gronnedal-Ika consists of foyaites, which are overlain by a variety of alkaline rocks, including nepheline syenite. Igaliq consists of

four intrusions, each containing nepheline syenite: North Qoroq, 1,270 Ma (Blaxland et al. 1978), South Qoroq, 1,160 Ma (Blaxland et al. 1978), Motzfeldt, 1,350 Ma (Paslick et al. 1993), and Igdlertfigssalik, 1,170 Ma (Blaxland et al. 1978).

Loch Borolan (Borralan), Scotland. Near Ledmur, Sutherland County, a 26-km², 300-m thick laccolith consists of quartz syenite, nepheline syenite (also called borolanite), and ultrabasic rocks (Shand 1939; Notholt 1979; Waters 2003). Typical borolanite in the southeastern end of the laccolith, which is about 430 Ma, is dark gray. A chemical analysis is given in Table 5.

Iivaara Complex, Finland. An intrusive core, 8.8 km², of melteigites, urtites, and ijolites, is surrounded by 100 to 300 m of fenite (Figure 7). The complex, 367 to 373 Ma in age (Kramm et al. 1993), can be divided into three zones: (1) outer fenite; (2) transitional rocks; and (3) the main alkaline intrusion, which consists of mixed and interlayered nepheline-clinopyroxene rocks: urtite (>70% nepheline); ijolite (50% to 70% nepheline); and melteigite (<50% nepheline). Economic development is hampered by the remoteness of the deposit and high iron content.

Koga Complex, Pakistan. Local glass and ceramic companies in Pakistan are expected to replace feldspar with nepheline syenite from the Koga, Buner District, Swat Himalayas, North West Frontier Province (NWFP) (Bolger 1995). The Koga Complex, 300 Ma old, consists of a carbonatite plug within a nepheline syenite (including ijolite) intrusion that is surrounded by fenite (Tilton, Bryce, and Mateen 1998). Sarhad Development Authority began pilot mining about 1993 and plans a capacity of 28,571 tpy of enriched nepheline syenite. Approximately 8,571 tpy of high-iron nepheline syenite could be produced for use by the steel, foundries, and refractory industries in Pakistan.

Sichuan, China. The Sichuan nepheline syenite in Shuiyue town, Anyang, Henan Province, contains more than 100 Mt of homogeneous material developed by Fintan Industrial Minerals Ltd. of Hong Kong. Sichuan Nanjiang Nonmetal Industry Co., currently the only company mining nepheline syenite in China (Bolger 1995), has built a 35,000-tpy modular plant and is able to make products suitable for the glass and ceramic industries (Industrial Minerals 2003). Twenty-two other nepheline syenite deposits have been found in China; the more important ones are at Nanjiang, Guangdong Fogang, and Yunnan Gejiu (Bolger 1995).

Uludag Deposit, Turkey. Matel Hammed Sanve Tic AS produces nepheline syenite from the Uludag deposit near Bursa Orhanli for making floor tile (Crossley 2003). A mine opened in 1989 that continued production into 1995 (Bolger 1995). Reserves are estimated at more than 40 Mt. The Hamit nepheline syenite pluton, central Anatolia, Turkey, is dark gray-green, medium-grained, and occasionally porphyritic with alkali feldspar.

Adapted from Kramm 1994.

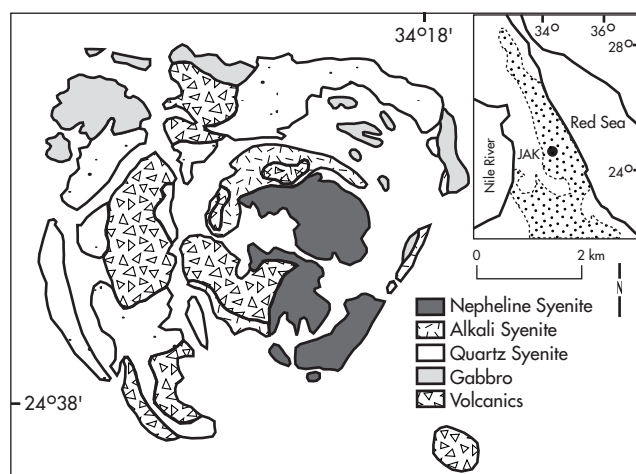

Figure 7. Geology of Iivaara, Finland

Norra Karr, Sweden. Examined for development of nepheline syenite, this complex consists of a variety of lithologies, including grennaite (fine grained, alkali feldspar, nepheline, aegirine, eudialyte, catapleite), lakarpite (arfvedsonite-albite-nepheline syenite), pulaskite, and kaxtorp (pectolite-eckermannite-aegirine-nepheline syenite) (Blaxland 1977). A chemical analysis is given in Table 5.

Elsewhere in Europe. Several deposits are scattered throughout Europe, but little information is known about them. Pyroxene foyaite is found at Pouzac, Pyrenees, France. Phonolite at Brenk, Eifel, in Germany has been mined for colored glass by Solvay Alkali GmbH (Bolger 1995). The Monchique nepheline syenite deposit in southwest Portugal was examined by Empresa de Desenvolvimento Mineiro SA in 1993. Because the deposit is high in iron, it would have to be magnetically separated (Bolger 1995). Keramos AS produces phonolite as a feldspar substitute from the Zelenice deposit in Mast, Czech Republic (Crossley 2003).

Iran. Kaleiber and Sarab nepheline syenite in the Alps and Himalayas in northern Iran is used for ceramics and glass and alumina (National Geoscience Database of Iran 2004).

Jabal Sawda, Saudi Arabia. Deposits range in composition from alkali-feldspar syenite to nepheline syenite and consist of perthitic alkali feldspar (60% to 90%) and nepheline (0% to 40%), with sodalite, very minor plagioclase, ferro-hastingsite, aegirine, augite, biotite, and opaque minerals. The K₂O content of the pluton ranges from 4% to 6%; the Na₂O content from 6% to 8%; and the FeO + Fe₂O₃ + MnO + MgO + TiO₂ content from 2% to 13% (Table 5; Liddicoat, Ramsay, and Hedge 1985). The deposits have undergone some bulk testing by Saudi ceramics companies and are currently under an exploration license granted to Maaden, the state mining company.

Adapted from Landoll, Foland, and Henderson 1994.

Figure 8. Geology of Jabal Abu Khuruq (JAK), Egypt

Jabal Abu Khuruq (Khuruq), Egypt. This nepheline syenite, approximately 130 km northeast of Aswan, was first studied from 1966 to 1969. It consists of an oval complex of ring dikes of alkalic syenite surrounding stocklike intrusions of nepheline syenite that were emplaced about 89 to 90 Ma (Figure 8; Hosterman, Patterson, and Good 1990; Landoll, Foland, and Henderson 1994). The nepheline syenites are divided into various types, including nepheline-bearing alkaline syenite, foyaite, and diorite (fine-grained, granular textured rock similar in composition to foyaite) (Landoll, Foland, and Henderson 1994).

The main deposit contains 26 Mt of nepheline syenite with an additional 40 to 50 Mt in other parts of the massif. The Russian National Aluminum-Magnesium Institute (VAMI) determined that the nepheline syenite, with an annual production of 100,000 t of alumina, would also yield 1.5 to 1.6 Mt of soda and 30,000 to 35,000 t of potash (Hosterman, Patterson, and Good 1990). A chemical analysis is given in Table 5.

Arroya Grande, Mexico. The Industria Penoles SA examined the Arroya Grande nepheline syenite near San Jose in the San Carlos Mountains for alumina. The nepheline syenite contains 60% orthoclase; 25% nepheline; 5% plagioclase; 1% augite; 8% magnetite; and 0.7% sphene (Hosterman, Patterson, and Good 1990). Associated rocks include diorite, pulaskite, phonolite dikes, and lamprophyres. The age is 27 to 29 Ma (Bloomfield and Cepeda-Davila 1973). Industria Penoles SA also investigated nepheline syenite for alumina at Ciudad Victoria, Tamaulipas (Minnes, Lefond, and Blair 1983).

Africa and Elsewhere. Several deposits are found in Africa, but little is known about them. Approximately 4.3 billion t of nepheline syenite, 538 Ma, have been estimated to occur in Meponda, Mozambique (Lulin et al. 1985). Several small, iron-rich nepheline syenite deposits have been mined for road material in South Africa. Deposits are also known to occur in Australia, Cameroon, Kirumba, Congo, Angola, and Lulwe Hill, Malawi.

TECHNOLOGY

Exploration Techniques

Because most nepheline syenite deposits are found in relatively shallow complexes of subvolcanic origin in well-defined rift-related continental provinces, and are associated with alkaline or carbonate complexes, these areas are favorable exploration targets. Many

nepheline syenite complexes form circular, zoned plutons, locally surrounded by fenite. Like many industrial mineral deposits, however, other factors must be considered in locating a commercial deposit, especially the proximity to potential markets and available inexpensive transportation.

Mineral exploration typically is expensive and can require 10 years or more of study before a decision is made to develop the deposit. Satellite images, remote sensing, geologic maps, geophysical studies, such as airborne gamma-ray spectrometry (Steenfelt 1991), magnetics, and gravity are useful in identifying regional alkaline provinces. Once the mineralized areas are identified, the explorationist conducts field examinations of the area. Detailed geologic maps are prepared to help characterize the rocks at the surface and to predict the types of rocks in the subsurface. Surface sampling, stripping, drilling and trenching, bulk sampling, and even panning are still used in the beginning phases of exploration. Samples are examined for favorable lithology and mineralogy and submitted to laboratories for chemical analyses. Petrographic studies are important in locating commercial nepheline syenite deposits. For instance, the use of cathodoluminescence can be used to identify the Fe^{+3} in feldspar, which typically characterizes an uneconomic deposit.

Despite the numerous exploration techniques available, ultimately the deposit must be drilled. Several drilling techniques are available that provide samples from depth of the potential deposit. In some cases, test or exploration pits or adits are dug in order to provide enough material for metallurgical testing or other purposes.

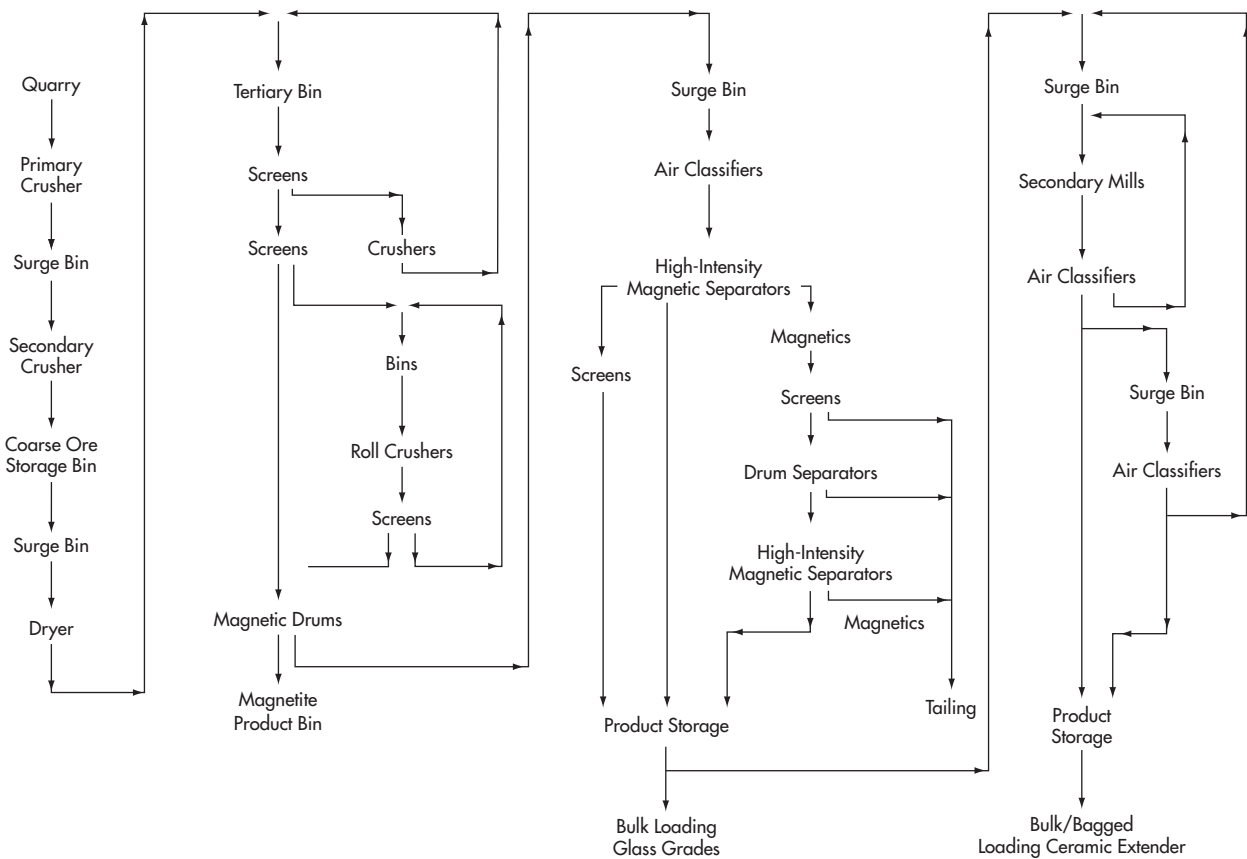

Mining

Nepheline syenite is normally extracted through standard open-pit or quarrying methods. The deposits are drilled and blasted and loaded on trucks with front-end loaders (Harben 2002). Mines in Norway and Russia also use underground methods. In Norway, underground room-and-pillar mining is employed, while, in Russia, block caving is used at a depth of 600 to 700 m. Rock mechanics research has shown that the optimum room size in Norway is 50 m long and 25 m wide. The underground deposits are drilled, blasted, crushed, and trucked via a spiral ramp (Harben 2002).

Processing

After the nepheline syenite is quarried, it is crushed, dried in rotary kilns, passed through flotation circuits and magnetic separators, and bagged or shipped in bulk (Moll 1996). Any iron must be removed from the finished product, especially for glass and ceramics use, by high-intensity magnetic separation. Fine-particle-size grades are separated by air classification. The raw material must have low moisture content for glass and ceramics use. A flow sheet is shown in Figure 9. Other uses of nepheline syenite can tolerate more iron in the finished product and typically require only crushing, screening, and sizing. In addition to the mines and processing facilities at Blue Mountain and Nephon, Unimin Canada has two plants near Toronto, which produce 15 to 20 grades of nepheline syenite. Chemical compositions of selected grades are shown in Tables 13 and 14. Of the 15 grades that North Cape Minerals (Unimin Corporation) produces in Norway, the three more popular products are glass-grade Altafloat, ceramics-grade Altaflux, and amber- and filler-grade Minex 10, 20, and 30 (Karlsen 1998). Glass grades are usually crushed to 600 μm , whereas ceramic and filler grades are finer than 75 μm (Moll 1996).

In Russia, nepheline syenite is used to produce aluminum (Figure 10). Where Al_2O_3 in nepheline syenite is more than 20%, $\text{Na}_2\text{O} + \text{K}_2\text{O}$ are less than 10%, and SiO_2 does not exceed 55%, nepheline syenite can be processed by sintering to produce alumina,

materials, riprap, and asphalt (Allen and Charsley 1968). Fines are used as a colorizing and fluxing agent in the manufacture of brick and as compaction fill.

Dimension Stone, Abrasive, Aggregate, and Other Uses

Nepheline syenites that have a pleasing appearance, can take a polish, and are relatively homogeneous without fractures can be used as a dimension stone. Many places use crushed nepheline syenite for aggregates. Other uses are as a mild abrasive for sand blasting, as welding fluxes in welding electrodes, and for extrusion and binding of coating fluxes.

Alumina

A significant amount of nepheline syenite is used in the manufacture of alumina and aluminum metal. Russia produces most of its aluminum needs from nepheline syenite because of the high alumina content in nepheline syenites. Several other countries also have examined nepheline syenite deposits for the purpose of manufacturing alumina and aluminum metal, but none have obtained the success of the Russians.

MARKETING

Consumption

Glassmaking is the major use for Canadian and Norwegian nepheline syenite, consuming approximately 70% of both countries' production. In addition, 28% of Norwegian output went to ceramics and 2% to filler. The Canadian mines supply approximately 15% of their additional output for ceramics and the balance for filler applications (Ciullo 1996). Most of the Russian production is for local manufacture of aluminum.

Exports

Canada and Norway are major exporters of nepheline syenite (Table 16), while the United States is one of the predominant importers (Table 17). Most of the remaining nepheline syenite production in the world is for local use. There are no reported exports of nepheline syenite from Russia.

Prices

Comparative price information is not readily available in today's competitive market for raw materials. Canadian nepheline syenite production was valued at C\$86.56/t in 2000 and has remained essentially flat over the last 5 years but is now more than double the 1992 price (Rogers 2002). Harben (2002) quoted prices as low-iron, 30-mesh, glass grade at C\$22/t; a higher-iron, colored-glass grade at C\$20 to C\$21/t; ceramic grade, 200 mesh, at C\$58 to C\$62/t; and bagged filler at C\$67 to C\$135/t.

Transportation and Distribution

As with many industrial minerals, transportation is critical to the competitiveness of a nepheline syenite deposit, and changes in transportation costs can make or break an operation. Most glass-grade nepheline syenite is sold in bulk and shipped by rail, with some truck haulage. For its product, Unimin Canada Ltd. leases hopper cars exclusively to a void contamination (Guillet 1994). Ceramic-grade nepheline syenite is bagged and shipped by rail or truck. Although all of the nepheline syenite from Norway is shipped by barge, transportation in other countries can be truck, rail, or barge.

Alternative Materials

For glass and ceramic uses, feldspar is the predominant competitor for nepheline syenite, although aplite and quartz-feldspar sands can

Table 15. Summary of feldspar and nepheline syenite performance in coatings

Dispersibility	Very good
Oil absorption/resin demand	Low
Chemical resistance	High
Weatherability	Very good
Tint strength	Low
Color development	Very good
Tint retention	Very good
Sandability (primers)	Poor
Chalking	Very good
Frosting	Very good
Abrasion resistance	Very good
Scrub resistance	Very good
Stain resistance	Very good
Mildew resistance	Very good

Table 16. Exports of nepheline syenite from Canada

Region	Value of Exports, 1995, C\$	Value of Exports, 2001, C\$
United States	37,292,000	43,903,000
Europe	943,000	1,916,000
Japan	483,000	1,109,000
Mexico	71,000	79,000
Other	3,520,000	4,371,000
Total	42,309,000	51,378,000

Adapted from Mining Association of Canada 2002.

be used in some cases. The choice between feldspar and nepheline syenite in glass and ceramics is tied to price, which is dependent on location and transportation costs. In U.S. markets, feldspar sources in Georgia and North Carolina and aplite in Virginia compete successfully with nepheline syenite. Increasing use of plastic containers will affect the use of glass and result in less demand for raw materials. A variety of alternative materials can be substituted for nepheline syenite in pigment and filler uses: calcium carbonate, kaolin, feldspar, silica, and talc. Most of the aluminum production in the world is from bauxite and recycling.

ECONOMIC OR COMPETITIVE FACTORS

Strong growth in the production of ceramics, particularly in Italy, Spain, and China, has been the main driver of the steady rise in nepheline syenite and feldspar demand over the past 20 years. Sales of flat glass and insulation-grade fiberglass are dependent on the health of the construction industry. When the construction industry is booming, demand for flat glass and fiberglass rises; when the industry is in recession, demand drops. A positive factor for nepheline syenite, processed or raw, is that it enters the United States and most countries free of tariffs, except for some countries that may levy value-added taxes (Minnes, Lefond, and Blair 1983; Guillet 1994). On the down side, energy costs have increased since 1999 and added as much as 20% to the cost of production (Rogers 2002). Starting in 2000, energy surcharges were instituted to recover the added costs due to increased energy costs.

Table 17. Imports of nepheline syenite for consumption in the United States

	1998	1999	2000	2001	2002
Imports, t	320,000	311,000	356,000	336,000	333,000
Value, US\$	24,100,000	23,200,000	24,800,000	24,100,000	26,100,000

Adapted from Potter 2001, 2002.

Also, recycling is reducing the need for raw materials. Approximately 34% of all glass containers produced are recycled; most bottles and jars contain 25% recycled glass (Rogers 2002). Ceramic recycling, however, is not significant in the North American market.

Regulatory and Environmental Concerns

Increasing pressure is being applied to the glass industry to reduce the use of glass products in order to reduce litter and municipal waste. In some areas, glass recycling, the reuse of glass containers, and use of alternative materials such as plastic are increasing.

Because its tailings are typically small and nontoxic, nepheline syenite operations pose no threat to the environment. Locally, dust can be a problem, which is easily controlled.

Classified as a Class 2A probable carcinogen in 1997 and as a Class 1 carcinogen in 1999, crystalline silica is becoming a serious health concern for feldspar and aplite producers. Since nepheline syenite is devoid of free silica, many nepheline syenite deposits that are not necessarily suitable for glass or ceramic production are being examined for potential abrasives uses.

OUTLOOK AND FUTURE TRENDS

For the near future, known resources of nepheline syenite are adequate to meet projected world demand. Competition between the major companies will remain high as a result of relatively low growth and low demand, and the price will probably remain flat, continuing a 5-year trend. It is possible, however, that increased ceramics production in Italy, Spain, Brazil, China, and Mexico could result in more demand for nepheline syenite. Clayworld now offers an iron-bearing nepheline syenite that has an established record of performance in the gres tile industry. Another factor is the housing market, which remained relatively robust throughout 2002 but is expected to slow in the near future. This trend could reduce demand for nepheline syenite and other raw materials for applications such as sanitary ware and ceramic tile. Increased use of plastics also could lower the demand for glass and ceramics.

Although increased glass recycling will result in a lower demand for nepheline syenite, glass manufacturers that use recycled materials are still confronted with incompatibility, inconsistency, and contamination issues. By mid-2002, many glass companies were predicting higher sales for the near future, boosted by increased beer and wine sales, as well as the introduction of new ready-to-drink low-alcohol "refreshers."

Container glass, which uses more feldspathic materials than other sectors of the glass industry, is facing strong competition from other forms of packaging. The positive environmental image of glass over other forms of packaging, particularly polyethylene terephthalate (PET) bottles, however, has helped glass to recover some of its lost market share.

Sales of flat glass and insulation-grade fiberglass are dependent on the health of the construction industry—in both the commercial construction and new housing sectors—and on the automobile industry. In Asia, flat- and fiberglass industries were severely affected by the fall in demand resulting from the Asian financial crisis of 1997–1998. In Europe and the United States, flat-

glass production continued to rise in the 1990s but stagnated in 2000. The strong competition between producers for the major ceramics markets of Italy and Spain is likely to keep European feldspar prices low, and the development of a potential new project in Egypt will probably have a negative effect on European prices. In the Far East, the development of the very large Chinese feldspar industry to support domestic demand and exports will exert a downward pressure on markets.

ACKNOWLEDGMENTS

The author thanks Amber Wooddyact, Luiza Gutierrez, and Alex Tamm for technical assistance. Unimin Corporation provided specifications sheets on their products (Table 14). This chapter draws from ongoing studies of the mineral resources at the New Mexico Bureau of Geology and Mineral Resources, a division of New Mexico Institute of Mining and Technology directed by state geologist Peter Scholle.

Nitrogen and Nitrates

Peter W. Harben and Carlos Theune

INTRODUCTION

Historically, deposits of guano or the waste from slaughterhouses and fish-processing plants have been used as crude fertilizers worldwide, and in northern Chile, natural nitrates have been used as fertilizer since the pre-Hispanic times of the Incas and the Atacama people. Chile remains the world's sole producer of natural nitrates. Modern exploitation of caliche deposits of natural sodium nitrate (*salitre*, saltpeter, nitratine, or simply natural nitrate [NaNO_3]) in the Atacama Desert began around 1830, although minor artisan exploitation is reported as early as 1810. The main use at that time was in the manufacture of gunpowder, with minor application as a fertilizer. Early in the eighteenth century, the territories containing nitrates belonged to Bolivia and Peru, but mainly Chilean, British, and German enterprises exploited the nitrates. After almost 40 years of disputes, a war between Chile and the alliance of Bolivia and Peru (Pacific or Saltpeter War), from 1879 to 1883, ended with Chile retaining all territories of the Tarapacá and Atacama regions (18°30' to 25° latitude south) and the establishment of definitive borders between Peru, Bolivia, and Chile.

Saltpeter became by far Chile's most important commercial enterprise for more than 100 years, peaking in 1912, when some 170 nitrate operations employed as many as 46,500 workers. Total saltpeter production from 1830 to 1929 was 90 Mt (95% NaNO_3) based on the mining of 1.13 billion t of caliche ore over a total surface of 5,000 km². Despite this prodigious production rate, the supply from Chile soon fell short of the growing demand for nitrogen products to be used in explosives, nylon, plastics, resins, and intensive agriculture, forcing the search for a large-scale replacement. Given that the earth's atmosphere consists of about 79.1% nitrogen by volume, 20.9% oxygen, 0.036% carbon dioxide, and trace amounts of other gases, extraction from the air was an obvious potential nitrogen source. What evolved was the fractional distillation of liquid air or natural gas to produce synthetic ammonia (NH_3) through the Haber-Bosch process (described later in this chapter). Cheaper synthetic ammonia production hit the saltpeter industry hard, and the world recession of 1929 was the final blow to the Chilean saltpeter industry. Although the María Elena and Pedro de Valdivia operations were built in 1925 and 1931, production of *salitre* remained at 1,000 ktpy until the late 1970s. The saltpeter industry revived in 1988, however, when the former state-owned Sociedad Química y Minera de Chile was privatized and evolved into SQM, the world's main producer of natural nitrates.

PRODUCTION AND TRADE

Ammonia

At approximately 150 Mtpy of contained N (as anhydrous ammonia), the modern production of nitrogen is dominated by the synthetic variety; just 1 Mtpy comes from natural nitrate production. Since the 1970s, new synthetic nitrogen fertilizer production has centered on natural-gas-rich countries of the Caribbean and Middle East plus several large consumers such as China, India, Indonesia, and Pakistan. The main producing regions are China with 22% of world production, North America with 18%, the former U.S.S.R. with 10%, Western Europe with 11%, Central Europe with 5%, South Asia with 15%, and the Near East with 5%. More than 80 countries produce 100+ Mtpy of contained N as anhydrous ammonia. More than half of the 11.5 Mtpy exported comes from Russia (22%), Trinidad and Tobago (14%), Ukraine (11%), and Canada (7%), and the major importers are the United States (31%), Western Europe (30%), and Asia (20%). Of the 43 Mtpy of contained N produced as urea, China and India account for 43%, and the United States and Canada a further 11%; about one quarter of 10 Mtpy exported comes from Russia/Ukraine and the Middle East, and almost 50% of imports go into Asia. A feature of international trade in fertilizer materials is the increased popularity of urea and the ammonium phosphates because of their high nutrient concentration.

Natural Nitrates

The primary product obtained from caliche is NaNO_3 , which in turn is processed to potassium nitrate (KNO_3) and specialty blends containing phosphates, sulfates, borates, and other nutrients. This makes it difficult to trace trade figures back to processed ore and obtained *salitre*, so in the tables in this chapter, total f.o.b. (free on board) value is much more relevant than tonnage.

As of 2004, three companies produce saltpeter and mixed fertilizer in Chile: SQM Holding, which includes SQM, SOQUIMICH Comercial (produces mixed fertilizers), and PCS Yumbes (formerly Miñera Yolanda); Compañía de Salitre y Yodo de Chile (COSAYACH); and ACF Minera. Exact figures are unavailable, but almost a fourth of total Chilean saltpeter production is for internal consumption.

Table 1 shows how Chilean exports of natural nitrates and specialty fertilizers have been steadily growing.

Table 1. Chilean nitrate exports, 2000–2003

Table 2. Destination of Chilean nitrate exports 2000–2003

Destination	2000, %	2001, %	2002, %	2003, %
Latin America	36.0	20.4	36.4	32.1
Europe	29.6	30.2	24.7	27.0
United States and Canada	18.0	25.2	23.3	21.6
Australia and Asia	15.9	20.3	11.5	15.0
South Africa	0.5	3.9	4.1	4.4

Table 2 shows that the world distribution of Chilean nitrate exports during 2000–2003 remained well balanced, in terms of f.o.b. value.

GEOLOGY

Natural nitrate ore in Chilean caliche occurs in three basic forms:

1. A mixed rock alluvial conglomerate (boulders to clay size) cemented by a mixture of salts
2. Salts filling basement rock (mostly volcanics) fractures and pores
3. Salts filling interstitial space between rock debris on the surface near piedmont layers

Commercially relevant is the conglomerate type, although fracture filling can reach grades of over 60% NaNO₃, but of restricted potential.

A standard section of a current mining face is shown in Figure 1.

Overburden (*chuca* or *chusca*) is commonly a friable desert dust, mainly built up by sulfates and silt. *Costra*, a conglomerate firmly cemented by clays and salt (NaCl), underlies it. In a graded transition below the *costra* is *caliche*. It is petrographically very similar to *costra*, but the cement in *caliche* is a salt mixture containing chlorides, nitrates, sulfates, iodates, borates, and other curiosities such as chromium salts. The bedrock, a similar conglomerate to *caliche*, is called *coba* if uncemented and *conjelo* if cemented. The transition is mostly graded.

Figure 1. Standard stratigraphical section of a caliche deposit

In general, the *caliche*—which is 1–2 m thick and white, brown, or black—consists of a variety of minerals, including nitrate (up to 40%), saltpeter (up to 17%), bloedite, glauberite, polyhalite, darapskite, lautarite, and dietzeite. Table 3 gives the weight percentages for common chemicals used in nitrate production.

Natural nitrate in economic concentrations occurs only in the Atacama Desert of northern Chile, one of the driest areas of the world (see Figure 2). *Caliche*-bearing areas are found within the central depression (central graben), between the coastal range and the pre-Andean range (see Figure 3).

Caliche ore deposits cover 2.8 million hectares in north-central Chile, and SQM holds the right to explore or exploit the mineral resources over roughly 60% of this area. This area contains an estimated 75% of Chile's *caliche* ore reserves. The total *caliche* potential of the Atacama Desert is unknown but is estimated to be several billion tons. In June 2003, SQM published the reserves information shown in Table 4.

Table 3. Weight percentages for common chemicals used in nitrate production

Chemical Name	Chemical Formula	wt %
Sodium nitrate	NaNO_3	6.5–8.5
Sodium chloride	NaCl	4–10
Sodium sulfate	Na_2SO_4	10–18
Calcium	Ca	0.5–4
Magnesium	Mg	0.3–1.3
Potassium	K	0.3–1.5
Potassium perchlorate	KClO_4	0.025–0.034
Borax	$\text{Na}_2\text{B}_4\text{O}_7$	0.4–0.6
Iodates (as iodine)	I_2	0.03–0.06
Lithium sulfate	Li_2SO_4	0.027 (approximate)
Water	H_2O	1–2

	510.4	6.9	414	1,698.9	6.9	441

TECHNOLOGY

Exploration Techniques

The main exploration techniques for natural nitrate are pitting and drilling, although some research has been done on geophysical methods. Grade and thickness distribution is irregular, requiring drilling patterns up to 400×400 m in the preliminary exploration stage. For evaluation purposes, the pattern is narrowed to as small as 50×50 m.

Although air reverse drilling (using a 5/4-in. tricon bit tool) has shown to be the most cost-efficient technique, grades must be checked by a few pit samplings. It seems that part of the nitrate salts are still blown out as fines through the annular rig space, thereby lowering the true grade. It is a quite complex problem because the difference is related to the drilled depth, so that the deeper the sample the lower the grade difference. It is advisable to elaborate grade correction curves adapted to a given exploration area. Drilling equipment should be mounted on a light all-wheel-drive truck, because the chusca surface can be extremely sticky.

Commonly, samples are taken every meter. The ignition test (Pavilo or Mecha) has proved to be very reliable in detecting where nitrate mineralization ends. This test involves scattering some of the milled sample (or drill dust) over an incandescent cotton rope; if the sample contains nitrates, it sparkles—the denser the sparkling, the higher the nitrate contents.

Nitrate Mining and Processing

Open-pit mining (called *rajos* in Chile) using dragline and power shovels yields an ore comprising 6.5%–8.5% NaNO_3 ; 4%–10% NaCl ; 10%–18% Na_2SO_4 ; 2%–7% Mg , Ca , K , B , and I ; 1–2% H_2O ; and 53%–69% gangue.

Processing is via the closed-circuit Guggenheim method: countercurrent leaching of crushed caliche ore in big vats with a heated leaching solution (at about 40°C), mainly composed of mother liquor from the nitrate crystallization plant, weak brines generated in the washing stages of the leaching cycle, and fresh water, to selectively dissolve out the sodium nitrate. On cooling, the sodium nitrate crystallizes out and is separated by a centrifuge, leaving the mother liquor to be recycled to the leaching vats.

SQM mines about 30 Mtpy of caliche ore from surface mines at Pedro de Valdivia, María Elena, Pampa Blanca, and Nueva Victoria. Typically, the caliche ore is found under a layer of overburden material that is between 0.5 and 1.5 m thick, in seams that are between 0.2 and 5 m thick. SQM processes the caliche ore at Pedro de Valdivia, María Elena, Pampa Blanca, and Nueva Victoria. At the first two production facilities the caliche ore is mechanically crushed to approximately a half inch (12 mm) in diameter, and the crushed ore is then transferred to nearby leaching vats. The crushing process

also produces fines (25%–30% by weight, including those coming from the mine) that after screening are leached separately from the crushed ore. The resulting solution is used to produce sodium nitrate, potassium nitrate (by reaction with potassium chloride at Coya Sur), iodine, and sodium sulfate.

At Pampa Blanca and Nueva Victoria, the caliche ore is heap leached without crushing. Leachates from both operations are treated for iodine extraction. At Pampa Blanca, the waste solutions from the iodine plants are transferred to solar ponds where rich nitrate salts are crystallized. After dry harvesting, the nitrate salts are hauled to Coya Sur to be used in the production of potassium nitrate.

The Haber–Bosch Process

In the Haber–Bosch process (named for its developers Fritz Haber, a German academic chemist, and Carl Bosch, an industrial colleague), natural gas (mainly methane [CH_4]) is compressed to 300–600 psi and desulfurized; in the presence of nickel catalysts at 815°C , the gas reacts with high-pressure steam to yield process gas, a mixture of hydrogen, carbon dioxide, and carbon monoxide. The process gas enters a secondary reformer containing nickel catalysts and injected compressed air; the oxygen in the air is consumed in exothermic reactions with hydrogen, carbon monoxide, and residual methane from the primary reformer. The gas contains sufficient nitrogen from the injected air for ammonia synthesis. The process gas reacts with steam to produce additional hydrogen and converts the carbon monoxide to carbon dioxide, which is separated as a by-product. Traces of carbon dioxide and carbon monoxide are removed by methanation, yielding pure hydrogen. The remaining gas mixture, or “synthesis gas,” consists of hydrogen and nitrogen in the correct ratio for ammonia synthesis, which takes place at high temperature and pressure and over a catalyst of iron oxide promoted by aluminum oxide, with potassium, calcium, or magnesium oxide.

The production of 1 ton of anhydrous ammonia containing 82% ammoniacal nitrogen (NH_3^+) requires 680,000–708,000 m^3 (24–25 MCF) natural gas feedstock and 425,000–453,000 m^3 (15–16 MCF) process gas. This ammonia is the starting point in the production of a range of nitrogen compounds that includes anhydrous ammonia, ammonium nitrate, urea, and ammonium sulfate.

The Haber–Bosch process is arguably one of the most important technological innovations of recent centuries (Smil 2000), and it helped Fritz Haber win a Nobel Prize for his work with nitrogen.

MARKETING

Fertilizer Uses

Fertilizers dominate the consumption of nitrogen compounds, and a diverse range of industrial uses makes up the balance. Nitrogen, a component of RNA and DNA, the genetic blueprints of life, is a primary nutrient (along with phosphorus and potassium) that encourages vigorous plant growth and increases yield. Nitrogen is the most widely used fertilizer nutrient, ahead of phosphorus and potassium. Cereals are estimated to account for 55% of fertilizer use worldwide in the following amounts: wheat (20%); corn (14%); rice (13%); barley (4%); oilseeds such as soybeans, oil palm, sunflower, linseed, and others (12%); pasture and hay at 11%; and vegetables, sugars, roots and tubers, and fibers each consuming 4%–5%. Plants take up elemental nitrogen only in the soluble nitrate or ammonium form (i.e., chemically bonded or fixed nitrogen).

Industrial Uses

Industrial sodium nitrate is used in a variety of industries where it is most often employed as an oxidizer. The main uses are as follows:

- **Adhesives:** used in starch formulations of water-soluble adhesives, wallpaper, and gummed tapes.
- **Ceramics:** used as a fluxing agent in enamel frit.
- **Charcoal briquettes:** added to a mixture of wood by-products, starch, and lignite to promote ignition and burning. The amount added depends on the type of wood and coal used, although it is typically 2%–3%. This market expanded rapidly during the 1980s and now probably stands at about 20,000–25,000 tpy.
- **Chemical compounds:** used as an oxidizer in pesticides, antifreeze, cement, and pigments, among others.
- **Explosives:** used as an oxidizer in water gel, slurry emulsion, and dynamite explosive formulations. Typical slurry explosives contain 10%–15% sodium nitrate, and dynamite can also contain sodium nitrate as an energy modifier.
- **Glass:** used as an oxidizer to remove impurities. Sodium nitrate also has a fluxing action that reduces the melting temperature, which in turn saves energy or improves throughput.
- **Health and nutrition:** used in the production of antibiotics and pharmaceuticals, and as a preservative in curing beef, bacon, and other meats.
- **Metallurgy:** used in heat-treatment salt baths where it changes the metallurgical structure to improve such mechanical properties as hardness and tensile strength. Sodium nitrate is used in the treatment of aluminum alloys, and in secondary refining (recycling), it is used to soften lead and to reduce impurities such as arsenic, antimony, and tin.
- **Water treatment:** used to supply oxygen to control and prevent hydrogen sulfide formation in wastewater that contains organic matter. Sodium nitrate can be used as an ingredient in water-softening agents and as an anticorrosive agent in boiler water.

All indications are that industrial sodium nitrate usage will continue to decline as more companies experiment with new non-industrial sodium nitrate batches. In broad terms, however, there is no one-to-one substitute for industrial sodium nitrate. The compound has unique characteristics that can only be partially replaced by other materials such as calcium nitrate, sodium sulfate, and ammonium nitrate. Although a direct replacement is not readily available, combinations of other batch materials can make replacement of industrial sodium nitrate possible, although these changes require lengthy testing and production changes. For the most part, many of the current users of industrial sodium nitrate have not been shocked enough by price or supply concerns to make the move to replace sodium nitrate. Only the glass industry has a real incentive to eliminate industrial sodium nitrate consumption to reduce oxides of nitrogen (NO_x) emissions.

The industrial market for potassium nitrate is fairly significant when compared with its overall consumption. The major industrial market is the color television (TV), lead/crystal, optical, and electronic glass markets. In TV glass, potassium nitrate is used in conjunction with potassium carbonate as required sources of K_2O needed for properly fluxing cathode ray tube glass in the presence of barium and strontium oxides, which are incorporated to screen out the x-rays generated. The ratio of nitrate to carbonate depends on the relative K_2O unit price between the two, and the limit of NO_x emissions allowed. Traditionally, this ratio has been about 1:3.

TV glass represents about 80% of total glass consumption of potassium nitrate. As a strong oxidizing agent, potassium nitrate is used in the manufacture of explosives and fireworks, and is also employed in making frits and in heat-treating steel and other metals.

Product Grades and Specifications

Ammonia-Based Products

One of the principal commercial forms of nitrogen is ammonia (NH_3), a colorless, nonflammable, liquefied gas with a characteristic sharp, penetrating odor that is highly irritating to the mucous membranes and eyes (it is the active product of smelling salts). Ammonia is the simplest stable compound of nitrogen and hydrogen. It is the source of approximately 97% of nitrogen fertilizer, which is either applied directly to the soil or converted into ammonium nitrate, ammonium phosphate, and other nitrogen compounds.

In manufacturing, ammonia is used to produce synthetic fibers such as nylon and rayon, as a catalyst in the production of synthetic resins, and to prevent coagulation of raw latex rubber. It neutralizes acidic by-products of petroleum refining and has metallurgical applications such as nitriding alloy sheets. Ammonia is a critical part of the ammonia-soda (Solvay) process to produce soda ash, and it is a portable source of hydrogen for welding. The pungent smell of ammonia is common in many household cleansers. Because ammonia is easily liquefied by compression or by cooling to about -33°C and because it absorbs substantial amounts of heat from its surroundings when returning to the gaseous state, it is used as a coolant in refrigerating and air-conditioning equipment. The polarity of NH_3 molecules and their ability to form hydrogen bonds help make ammonia highly soluble in water, forming an alkaline solution of ammonium hydroxide with its characteristic alkaline (basic) properties and ability to combine with many chemicals.

Ammonia serves as a starting material for the production of many commercially important nitrogen compounds. One of the most important is urea, $\text{CO}(\text{NH}_2)_2$, formed when ammonia is treated with carbon dioxide at $132^\circ\text{--}182^\circ\text{C}$ under high pressure; it is used as a direct application fertilizer (46-0-0) or in urea-ammonium nitrate (UAN) solutions, in animal feed, in urea-formaldehyde resin and melamine production, in textile treatment, and in pharmaceuticals. An important form of nitrogen derived from ammonia is monoammonium phosphate, $\text{NH}_4\text{H}_2\text{PO}_4$, or MAP (11-48-0), and diammonium phosphate, $(\text{NH}_4)_2\text{HPO}_4$, or DAP (18-46-0). Its main use is as a fertilizer; it is also used as a food additive.

Ammonia is treated with various mineral acids to produce critical ammonium chemicals. Ammonium nitrate, NH_4NO_3 (33.5-0-0), manufactured from nitric acid, is used in explosives such as ammonium nitrate and fuel oil (ANFO) and nitroglycerine, in the manufacture of glass and frit, as an ingredient in charcoal briquettes, in metal treatment, in water treatment, and as a feedstock in the manufacture of adipic acid, nitrobenzene, and toluene diisocyanate. Ammonium sulfate, $(\text{NH}_4)_2\text{SO}_4$ (21-0-0), from sulfuric acid, is used as a direct application fertilizer, in a blended nitrogen fertilizer containing 24% sulfur, as a fire retardant, in the manufacture of viscose rayon, and as a chemical feedstock. Most ammonium sulfate is a by-product of the production of caprolactam (the intermediate for nylon 6 fiber and plastics), the removal of ammonia from coking coal in the steel industry, and the Sedema process of chemical manganese dioxide production. Ammonium chloride, NH_4Cl , or ammoniac salt, is produced from hydrochloric acid; it is used in galvanizing and soldering fluxes, as an electrolyte in zinc-graphite dry-cell batteries, and in the preparation of alkaline cleansers. Other chemicals derived from ammonia or its derivatives include calcium nitrate, ammonium dichromate, hydrazine and sodium cyanide,

nitric acid, antimony nitrate, cyclohexanone, magnesium nitrate, manganese nitrate, nitrobenzene, nitroglycerin, nitrophosphates, and trinitrotoluene.

Caliche Ore-Based Products

The caliche ore mined in Chile is used as a feedstock in the manufacture of sodium nitrate (16-0-0), sodium potassium nitrate (15-0-14), and prilled (13.5-0-44) and standard potassium nitrate (13.5-0-45); in numerous blended specialty fertilizers used for higher value crops such as vegetables, tobacco, fruits, cereals, sugar beets, and cotton; and for hydroponics or greenhouses. Fertilizer based on 100% nitrate nitrogen is virtually chloride free and slightly alkaline, easy to handle, nonhygroscopic, and 100% water-soluble, making it suitable as a fast-nutrient-release fertilizer. It is reported to help alleviate prolonged greenness and delayed curing in tobacco and to reduce the risk of late season growth, boll shed, and insect damage in cotton. It encourages early maturity, high yields, increased storage life, and transit qualities in vegetables, and it improves the sugar content and facilitates the uptake of Ca, Mg, and K in citrus fruit.

Sodium nitrate, which contains 16% nitrogen and 2.6% sodium plus trace elements such as boron and magnesium, is fully water soluble, making it suitable as a fast-nutrient-release fertilizer. It contains 100% nitrate nitrogen, which is available for root uptake without chemical transformation and can supply the sodium requirements for many crops where the sodium can replace part of the plant's potassium requirement, thereby reducing costs. Sodium nitrate is used, for example, as a quick-acting top-dress nitrogen fertilizer, which strengthens crops and increases their resistance to pests and disease. The main market for sodium nitrate, however, is industrial; it acts as a secondary oxidizer in slurry water gel, emulsion, and dynamite formulations; aids in the removal of glass batch impurities where fine oxidizing conditions are necessary; contributes to steel tempering, heat treatment of aluminum alloy, and the annealing of copper; and acts as a scavenger for secondary lead and as a food additive to preserve color and inhibit botulism.

Potassium sodium nitrate, containing 15% nitrogen as nitrate and 14% chlorine-free potassium, has a high solubility and a slight alkaline reaction in soil. It is quick acting and chlorine-free, and has a balanced nitrogen and potassium ratio of 1:1. Prilled potassium sodium nitrate is used for sidedressing tobacco, vegetables, fruits, and flowers, and for topdressing small grains in early spring.

NPK Specialty Blend fertilizers (produced by SQM) are bulk-blended mixtures with part or all of their nitrogen as nitrate, chlorine-free potassium, and optional secondary or minor element concentrations. These products are manufactured on demand specifically for crops that are sensitive to ammonia or chlorine in the soil. These blends—SQM produces more than 200—are used as base fertilizers during planting of crops such as potatoes, vegetables, and tobacco and as a sidedressing for citrus, coffee, etc.

Packaging

In general, fertilizers are sold in bulk to large farms or agro-companies and in 50- or 25-kg (100-lb or 50-lb) plastic bags to smaller consumers. Potassium nitrate destined for domestic fertilizer usage in the United States is generally shipped bulk in 100-t covered hopper cars, and in palletized 50-kg (100-lb) bags and 1,000-kg (1-t) supersacks. Table 5 shows the typical packaging for sodium nitrate for industrial uses.

Shipments of industrial-grade potassium nitrate to the TV-glass industry are generally in 100-t bulk railcars, whereas shipments to smaller industrial users are primarily in 50-kg bags and 1,000-kg supersacks.

Table 5. Typical packaging for sodium nitrate

Grade	Import Package	Finished Goods Package
Industrial-grade sodium nitrate	Bulk	Bulk, 50 kg, 100 lb, 1 t
Technical-grade sodium nitrate	1-t supersack	50 kg, 100 lb, 1 t
Refined-grade sodium nitrate	1-t supersack	50 kg, 100 lb, 1 t

Transportation

In Chile, nitrate and related products are transported by road or rail to consumers. Because much of the production is exported, there are several important ports, including Iquique and Antofagasta, plus Tocopilla, where SQM operates a dedicated port for bulk or packaged shipments to customers and distributors.

Specifications

Urea contains 46% N; ammonium nitrate, 33.5% N; ammonium sulfate, 21% N; MAP, 13% N and 52% P; DAP, 18% N and 20% P; and aqueous ammonia, a minimum of 29.4% NH_3 . Potassium nitrate has a minimum chemical analysis of 13% N and 44% K_2O (potassium oxide), although most grades sold contain 13.0%–13.8% N and 45%–46% K_2O ; chloride levels are very low, usually less than 0.01%. It is available as a prilled (nominal 6×20 mesh) direct application, and bulk blending and soluble, or as a crystalline (nominal 20×120 mesh) product for liquid fertilizer applications and the manufacture of granulated N-P-K fertilizers. Higher purity forms (slightly lower chloride, sodium, and other metal contaminants) are required for industrial applications.

ECONOMIC OR COMPETITIVE FACTORS

Modern nitrate production is accompanied by iodine production, and in fact iodine may be considered the primary product with the nitrates as coproducts. Crystallized sodium sulfate decahydrate (Glauber salt) is produced from the leaching solutions remaining after the iodine production process and is used to produce anhydrous sodium sulfate.

REGULATORY AND ENVIRONMENTAL CONSIDERATIONS

Anhydrous ammonia is not a poison and has no cumulative toxic effects on the human body. Ammonia vapor is considered to be “life threatening,” however, when exposure levels reach 2,500–6,500 ppm for up to 30 min or “rapidly fatal” if exposure levels reach 5,000–10,000 ppm for up to 30 min. The U.S. Environmental Protection Agency’s (EPA’s) interim acute exposure guideline levels (AGELs) include an AGEL-2 for ammonia of 160 ppm for 30 min and 110 ppm for 60 min (AGEL-2 is defined as the concentration of an airborne substance at or above which it is predicted that the general population, including sensitive but not hypersusceptible individuals, could experience irreversible or other serious long-lasting effects or impaired ability to escape). Ammonia is not combustible except when its concentration in the air is 16%–25% at 849°C or higher. It does require special handling because anhydrous ammonia turns into a colorless, pungent, hazardous gas under atmospheric conditions. One industry reference for storage and handling is K61.1, written by The Fertilizer Institute (TFI) and issued by the American National Standards Institute (ANSI). In 1990, the U.S. Department of Transportation classified anhydrous ammonia as a nonflammable gas linked to a required “inhalation hazard” label and as a Division 2.2 nonflammable, nonpoisonous compressed gas for domestic shipments. International shipments, however, were classified as a Division 2.3 poisonous gas, consistent with UN regulations. Ammonia is stored in carbon-steel cylindrical

tanks at atmospheric pressure and -2°C , and shipped in tank railcars or trucks under pressure as a liquid, by refrigerated barges and ocean vessels, or by pipeline.

Nitrogen compounds are an environmental concern in that overfertilization and the subsequent runoff of excess fertilizer can contribute to nitrogen accumulation in watersheds, which has been theorized to cause hypoxic zones (such as in the Gulf of Mexico during the summer).

PRICES

Because the choice of fertilizer is an agronomic decision rather than an economic decision, the demand for specialty fertilizers is inelastic with regard to price. If the price of fertilizer increases, the farmer still must purchase it if he intends to continue to grow the crop. This is particularly true for nitrogen, which is soluble and disappears quickly compared with both P and K, which can remain in the soil for some time. Therefore, there may be a slight drop in P and K initially when fertilizer prices rise, but the cutback cannot be maintained for any significant length of time.

Prices are chiefly a result of the supply-and-demand balance. In the case of potassium nitrate, Chile, the United States, and Israel control the volume of supply available on the market. On the demand side, the types of farming and the range of crops produced have an influence on fertilizer use. Tobacco production is declining in the United States but is increasing in China. As with most markets, the actions of China will have a major impact on fertilizer demand and pricing.

Urea is the main nitrogen fertilizer and can be an alternative to the use of nitrate. There will be a price relationship between urea and nitrate at which farmers will decide to switch in either direction. History has shown that nitrate prices are less volatile than urea prices. A price relationship is more evident in the sodium nitrate markets in Chile and China. In Chile, SQM has set the price of sodium nitrate at different levels relative to urea from season to season (mainly from 1980 through 1987), and this has been very useful for establishing a relationship that extends from a 6% share of the nitrogen market for nitrate when its price per unit of nitrogen was 2.5 times that of urea, to 48% of the nitrogen market when its price per unit of nitrogen was 1.1 times that of urea.

Negotiations to sell sodium nitrate to China are based on nitrate at twice the urea price per unit of nitrogen. As a result, most of the negotiations revolve around the urea price to be used in the comparison, which makes the situation challenging for the seller.

Worldwide, the price of potassium nitrate is set by exports from Chile on an f.o.b. port basis in US dollars per ton. These prices peaked at just about \$300/t in 1997. Since then, they declined to less than \$280/t in 1999 and to \$250/t or less based on exports in 2000 and 2003.

For industrial nitrates, price levels are determined by industry type—based on exports, the average price for sodium nitrate was \$180/t f.o.b. Chilean port in 2002 and 2003.

Actual pricing in the United States for most industrial-grade potassium nitrate is \$450–\$500/st delivered to the customer. As the largest consumer, the TV-glass industry pays the lowest price, and smaller consumers pay the higher price. TV glassmakers purchase by 2- to 3-year contracts, with target prices subject to meet-or-release clauses. Other sales are mostly consummated on a spot basis, based on quoted or negotiated prices.

OUTLOOK AND FUTURE TRENDS

Demand Drivers

Western Europe and North America have generally accounted for the bulk of the demand for specialty fertilizers such as potassium

nitrate and potassium sulfate. Latin America and Asia (particularly China), however, hold the key to future demand growth based on population growth and the increasing sophistication of farming. In addition, China is the largest producer of tobacco, which is the largest consumer of specialty fertilizers. Worldwide, specialty fertilizer demand will increase with the increased popularity of fruits and vegetables, the need for intensive farming close to urban areas, and the increased use of innovative farming techniques such as fertigation and micro-irrigation. Demand should also increase as farming in areas with high chloride soils becomes necessary. Periodic fluctuations in demand occur because of factors such as weather conditions in the growing areas (the El Niño effect), changes in government agricultural support policies, commodity price and foreign exchange fluctuations, and changes in the crops grown or in the N-P-K ratios used.

Conventional use of sodium nitrate in explosives, BBQ briquettes, and glass appears to be declining as less nitrate is used per unit of product, and, in some cases, environmental concerns are encouraging elimination. In the glass industry, there is a real push to eliminate industrial sodium nitrate to reduce NO_x emissions. The compound has unique characteristics, however, that can only be partially replaced by other materials such as calcium nitrate, sodium sulfate, and ammonium nitrate. Future growth has to rely on the development of new uses—in particular, water treatment and alternative energy.

Market Channels

Today, as sole suppliers of natural nitrates, Chilean nitrate producers face a situation—driven by market forces—in which they have a very small piece of the fertilizer market, and the only way to grow is to expand into other regions producing the same crops that currently use nitrates. That implies a significant marketing effort intimately related to the distribution channels.

Nitrate producers have to be much closer to the end user than producers of commodity fertilizers. For example, in both Brazil and Chile, PCS Sales (or Canpotex) sells potassium chloride using a sales representative. This company officer and his secretary receive calls from fertilizer importers (6 in Chile and 10 in Brazil) and act as coordinators between the producer (PCS) and the importer for setting the quantity, price, timing, and conditions of a shipment (usually at least 10,000 t of product).

SQM has its own subsidiary (Soquicom) in Chile for the import of any kind of fertilizer and for the sale of nitrates. This subsidiary contracts out a chain of local and national distributors that carry, on consignment, fertilizer products imported and produced by SQM. Soquicom has divided Chile into seven zones, and each has an office that manages sales and produces market intelligence. SQM agronomists in each office work with the local distributors to establish the amounts needed and dates delivery is required. They organize local marketing (directly for big farmers or collectively for the smaller ones), which basically consists of showing them the results of agronomical trials for their areas of interest. SQM's marketing department collaborates with universities and governmental institutions for these trials that are designed to show the advantages of nitrates over other fertilizers. There are also local trials, conducted by the local office in collaboration with large farmers. The local offices also provide information on the competition, both products (calcium nitrate) and fertilizers imported by other companies. They also provide information about developments in local farming and the performance of distributors.

Only a limited number of countries produce nitrates, iodine, and lithium, and therefore a significant proportion is exported: virtually all the natural sodium nitrate exported comes from Chile.

More than 90% of SQM's specialty fertilizers are exported, with a fairly even distribution, to more than 100 countries: approximately 20% is sold in South and Central America, 22% in North America, 19% in Europe, and 21% in the rest of the world. No single customer accounts for more than 4% of specialty fertilizer sales, and the combined sales of the 10 largest customers account for less than 21% of total sales.

Almost all iodine is exported from Chile, including some 2,000 tpy of iodine derivatives that are processed locally.

Olivine

Peter W. Harben and Corky Smith Jr.

Olivine is a magnesium-iron silicate mineral formed deep in the upper mantle. It is used chemically as a source of magnesia combined with silica and physically for uses requiring hardness and resilience. Relatively few countries and still fewer companies produce it in commercial quantities. Overall, Norway dominates commercial production, and metallurgy dominates consumption.

GEOLOGY

Olivine is a common mineral in the low-silica rocks making up the oceanic crust. It is particularly common in pre-Ordovician to Tertiary basalts and other mafic igneous rocks and is the essential mineral of peridotite. Rock containing more than 90% olivine is known as dunite, named for its type locality in Dun Mountain, Nelson, New Zealand. A medium- to coarse-grained crystalline rock, dunite is generally reddish brown when weathered. Fresh, unweathered dunite is, however, relatively rare because it readily takes up water and alters to oxides and serpentine. Deposits commonly contain 92% olivine, 5% pyroxene, and 1% spinel, chromite, and magnetite, along with 2% secondary minerals such as chlorite, serpentine, talc, vermiculite, and limonite. Olivine also occurs in basic igneous rocks such as olivine gabbro, basalt, and diabase (dolerite). Commercial deposits of olivine, however, are generally restricted to dunite bodies of the alpine type that intruded from the upper mantle into the upper lithosphere along deep faults in partly crystallized form (Harben and Kuzvart 1997). Associated minerals are diopside, spinel, plagioclase feldspars, chromite, magnetite, talc, hornblende, serpentine, iron-nickel meteorites, and augite.

Magnesium-rich olivine forms through the thermal metamorphism of siliceous limestone and dolomite. Fayalite is more common in regionally metamorphosed iron-rich sediments.

Mineralogy

Olivine represents an isomorphous solid solution series of orthosilicate minerals rather than a single mineral and has the general formula R_2SiO_4 , where R is iron or magnesium. The magnesium end member is forsterite, Mg_2SiO_4 , named for Adolarius Jacob Forster (1739–1806), an English mineral collector, and the iron end member is fayalite, Fe_2SiO_4 , named for its type locality at Fayal Island in the Azores. This gives a general designation of $(MgFe)_2SiO_4$ or $2(Mg, Fe)O \cdot SiO_2$. Olivine comprising more than 15% fayalite and less than 85% forsterite is considered unsuitable for most industrial uses: the iron content makes it less refractory because Mg_2SiO_4 melts at 1,890°C compared to 1,205°C for Fe_2SiO_4 .

Chemical and Physical Properties

Olivine (forsterite) is commonly yellowish green with a vitreous luster. It also occurs as light or olive-green yellow. The Mohs hardness is 6.5 to 7.0, the cleavage is poor, and the fracture is conchoidal. The specific gravity is approximately 3.2 when pure Mg_2SiO_4 and rises with increasing iron content.

DISTRIBUTION OF WORLD DEPOSITS

Commercial olivine has two main occurrences:

1. Dunite, a medium- to coarse-grained igneous rock with 90% or more of its volume made up of olivine
2. Serpentine, composed mainly of the mineral serpentine, $(Mg, Fe)_3Si_2O_5(OH)_4$, from kimberlites, ophiolites, and gabbros that originally had large amounts of olivine

Despite their obvious geological differences, the names olivine, dunite, and serpentine are often used interchangeably. Deposits commonly contain more than 90% olivine plus pyroxene, spinel, chromite, and magnetite together with secondary minerals such as chlorite, serpentine, talc, vermiculite, and limonite. Because fresh, unweathered olivine is a rarity, most commercial deposits are based on the less attractive altered serpentine.

The world's production capacity of olivine, dunite, and serpentine is estimated at some 8 Mtpy, of which about half is high-quality olivine almost exclusively from Norway. This source dominates trade via its deep-water ports and a long-standing distribution system. Production elsewhere is mainly based on serpentine, for example, in Argentina, Austria, Brazil, Italy, Japan, Korea, Mexico, Spain, Taiwan, and the United States (see Table 1).

Norway

Olivine production in Norway of approximately 3.5 Mtpy is derived from dunite bodies within the Fjordane Complex, south of Ålesund, in the Sunnmøre-Nordfjord District in the west of the country. These deposits are the largest in the world, estimated to contain 2,000 Mt of olivine within 6 km². The average mineral content of the dunite is 92% olivine, 5% pyroxene and serpentine, 1.5% chlorite, and 1% spinel; the mineralogical composition of the olivine is 94% forsterite and 6% fayalite (Olerud 1995).

The world's largest olivine producer is A/S Olivin, owned by North Cape Minerals AS, which itself is 64% owned by Unimin Corp. and the balance by Franzefoss Bruk AS of Norway. The company owns the Bryggja, Nordfjord, operation (underground)

Table 1. World production of olivine*

Country	Production, ktpy
Australia	80
Austria	20
Brazil	350
China	350–500
Italy	100
Japan	2,000
Mexico	150
Norway	3,500
South Korea	500
Spain	700
Taiwan	400
Turkey	150
United States	100
Total	8,050

* Commonwealth of Independent States olivine production not included because of a lack of reliable data.

and two operations at Åheim (Å Imeklovdaalen), south of Ålesund, comprising More (surface) and Rauber gvik, Romsdal (underground), the latter through Olivin's subsidiary Industrimineraler AS. Bryggja and Rauber gvik have a combined production capacity of 500,000 tpy, whereas the Åheim mine has a capacity of 3.8 Mtpy with output carried via a 4-km-long conveyor in a tunnel to the plant next to the harbor. Slag conditioning in the iron and steel industry accounts for 90% of sales, with the balance used in foundries, refractories, and abrasives. Steinsvik Olivin AS is a potential olivine producer in Norway based on a deposit at Vassbakkedalen, above Steinsvik in Dalsfjord. The deposit is 2 km from the North Sea, and analyses of samples have apparently indicated olivine quality similar to that of Åheim. The total size of the reserves has been estimated at 25 million m³, with MgO content ranging from 46.5% to 49.0%. The project is designed to ramp up from an initial production of 250,000 to 350,000 tpy (O'Driscoll 2004).

Italy

Nuova Cives Srl mines an olivine deposit near Turin in the municipalities of Castellamonte, Vidracco, and Baldissero Canavese in the north of Italy. The 75-km² outcrop area hosts more than 100 Mt of reserves, grading 95% to 97% olivine. The capacity is some 300,000 tpy of crude ore, with the plant at Vidracco capable of producing 250,000 tpy. About 40% is used in refractories and metallurgical applications; 10% in iron ore production; 15% in foundry; 20% in blasting abrasives; 10% in bituminous products, special paints, and ceramics; and 5% in road construction (O'Driscoll 2004).

Spain

In the province of La Coruña, in Galicia in northwestern Spain, Pasek España SA produces about 700,000 tpy of dunite for slag conditioning, refractories, and aggregates. Pasek España is a wholly owned subsidiary of Belgium's Pasek Group and focuses on the refractories market. Pasek also has operations in France and Brazil.

Turkey

Turkey produces about 150,000 tpy of olivine from a number of small- to medium-scale producers. The leading producer is Beyk-

rom Mining Inc. in Beysehir, Konya, with a plant capacity of 150,000 tpy. The main markets are eccentric bottom-tapping (EBT) taphole filler, slag conditioner for steel, refractories, sand blasting, foundry, and also fines for other markets. Beykrom's target markets are in the Mediterranean and Middle East regions. Potential producers include Olivin Mineral AS and Ado Mining.

Japan

Japan is the world's second largest olivine producer, after Norway, with an output of some 2 Mtpy. Much of this is derived from extensive deposits of mostly serpentine in the Horoman Hill region in Hokkaido, which supplies the domestic steel and foundry industry. As many as 30 producers have the capability of producing as much as 5 Mtpy of all forms of olivine, much of which is used in construction. The largest is Toho Olivine Industrial Co. Ltd.'s operation on Horoman Hill on the northern island of Hokkaido, which produces about 300,000 tpy of olivine. This is the largest deposit in Japan, with reserves estimated at 100 Mt.

China

Olivine production in Henan Province in central China is based on deposits of forsterite in southwest Henan, in Xixia County, west of Nangyang, and in Yubian County. The ore body is approximately 7.5 × 1.1 km in size, with ore reserves of more than 100 Mt and mineral reserves of 9 Mt. The more than 30 mining sites have production capacities ranging from 10,000 to 50,000 tpy. Henan olivine production is estimated to be 350,000 to 500,000 tpy of high MgO (47.26%) grades used as a slag conditioner, foundry sand, refractories, and other uses. The main producers are Henan Mines & Refractory Corp. and Nanchuan Minerals Group.

United States

Olivine production in the United States is restricted to the Cascade Mountains of Washington State and the Smoky Mountains of North Carolina. Deposits in Washington are superior in quality but much farther from most markets. Output is modest at about 100,000 tpy.

The center of production in northwestern Washington is at Twin Sisters Mountain in Whatcom and Skagit counties, 32 km east of Bellingham. A 90-km² elliptical body of dunite, the largest in the Cascade belt at 200 billion t, is composed almost entirely of unaltered olivine (W. Moen, personal communication). The geological setting of the area is dominated by three thrust sheets, the youngest of which brings greenschist and phyllite, thought to be pre-Jurassic, over Paleozoic rocks. The Twin Sisters mass is an enstatite-bearing dunite that weathers reddish brown. Unaltered rock consists of olivine, enstatite, chromite, and clinopyroxene. Forsterite is dominant throughout the mass. Unimin Corp. accounts for the bulk of olivine production, working a talus accumulation at the base of Twin Sisters Mountain, and Olivine Corporation operates a mine near Bellingham, Washington. Production capacity is 50,000 tpy. Industry sources report that Olivine Corporation mines about 40,000 tpy of olivine from its Sven Larsen quarry in Whatcom County, which is used to produce olivine foundry sand for manganese steel castings. In addition, some material is shipped to Unimin Corp.'s plant at Hamilton, which produces casting sands and other refractory products.

Several large masses of dunite have been recognized in a belt extending from Watauga County, North Carolina, southwestward to White County, Georgia, a distance of about 280 km. Two main districts, the Webster-Balsam District in Jackson County and the Spruce Pine District in Yancey and Mitchell counties, have historically produced most of North Carolina's olivine. The deposits contain 50% to 90% olivine. The dunite bodies occur in two main forms—lenticular intrusions with the long axis parallel to the regional schistosity and,

more rarely, ring dikes. The core of the bodies, accounting for about half the volume, consists of relatively unaltered olivine; the outer zones and some faulted zones within the core are partially altered to serpentine and talc. The largest of these bodies contains an estimated 300 Mt of dunite, and the mineralogy is remarkably consistent. The now-closed Addie deposit, 56 km southwest of Asheville, North Carolina, consists of a highly laminated dunite alternating with talc, chlorite, and other secondary minerals formed through the action of hydrothermal solutions. Masses of dunite little affected by this metamorphism were the economic zones.

Recent production has been limited to the Unimin Daybrook mine near Burnsville in Yancey County with an output of some 100,000 tpy.

Other Countries

Magnolit GmbH produces some 120,000 tpy of serpentinized olivine from an open pit at St. Stefan ob Leoben in Austria. Because the product contains from 40% to 70% serpentine, it has to be calcined and graded for commercial use.

In Mexico, Regio Cal SA de CV produces about 25,000 tpy of dunite and serpentine at Mag Minas de Tamaulipas, Ciudad Victoria, Tamaulipas.

Black Mountain Mineral (Pvt) Ltd produces 30,000 to 40,000 tpy of olivine from a quarry at Lashaker, some 60 km from Mingora in Swat, Pakistan.

Olivine production in the former U.S.S.R. is centered in the Pamir Mountains.

TECHNOLOGY

The positive relief of dunites and the fact that they support sparse vegetation facilitate prospecting. Core drilling is often difficult because of the presence of serpentinized zones, and therefore percussion drilling with compressed air (the so-called "down the hole" method) is used.

Except for one room-and-pillar underground operation at Briggja in Norway, mining of olivine or dunite is by open-pit methods. Using bench heights of 3 to 9 m, drilling and blasting is generally supplemented by secondary drop-ball work to reduce the size of the boulders. Shovels or front-end loaders load trucks transport the feed to the local plant, where it is reduced to -40 mm material using a primary jaw or cone crusher. The resulting product may be screened to a -40 +10 mm commercial product or reduced further by cone, impact, or roll crushers or by ball mills. Some producers such as those in North Carolina use wet processing and gravity separation. In Australia the dunite is calcined in rotary kilns at 1,650°C to produce grades suitable for refractory and foundry applications.

USES

Olivine is a commercial source of magnesia combined with silica used mainly in metallurgy, where it is utilized as slag conditioner, refractory, and foundry sand, and as a fertilizer. Its physical attributes are appropriate for abrasives, filler applications, and several miscellaneous uses. According to the U.S. Geological Survey (USGS), in 2004, foundry uses accounted for 91% of olivine use in the United States, with sandblasting and other abrasive uses at 5%, and refracting applications at 4% (Kramer 2005). Gem-quality olivine is known as chrysolite (light yellowish-green olivine), evening emerald (olivine's gemstone variety), and most commonly peridot because of the inclusions and cloudy nature of large stones, peridot is the magnesium-rich forsterite with a unique green-yellow color caused by the presence of iron ions plus trace nickel and chromium.

Metallurgy

By far the largest market for olivine is as a slag conditioner in blast and electric-arc furnaces. In addition to conditioning the slag, the olivine controls the basicity through alkali recirculation reduction within the furnace because of the formation of stable magnesium alkali silicates. In addition, its higher reaction temperature reduces low-temperature breakdown and swelling of the burden, thus maintaining permeability and reducing coke consumption. The olivine may be added directly to the blast furnace charge as lump (10 to 40 mm), added as a sinter feed (3 to 6 mm), or mixed with low-silica iron-ore fines and pressed into pellets. Each form has its pros and cons. As a lump added directly to the furnace, olivine can replace some of the limestone and dolomite flux in the reduction of the iron ore. Compared with dolomite, olivine has a higher MgO content (requires less material for a given MgO level), higher MgO:SiO₂ ratio (thus allowing MgO levels to be raised without changing the basicity of the slag), and lower loss on ignition (LOI) of 0.3% to 0.7%, which conserves the energy required to drive off unwanted carbon dioxide.

With an initial sintering temperature of 1,450°C and fusion at 1,665° to 1,743°C, olivine is well suited as a refractory. Added advantages include a low and uniform coefficient of thermal expansion; good resistance to thermal shock, spalling, and slag attack; and a high green strength. Therefore olivine is used in the manufacture of magnesia (forsterite) refractory bricks; in spraying, ramming, and gunning mixes; as EBT tap hole filler for electrical arc furnaces; and in precast refractory linings for incinerators. Because of its ability to minimize generation of harmful gases, olivine sand is used to line siloburners used to dispose of hospital waste and other toxic wastes.

The refractory properties plus its lower free-silica content and strong resistance to metal attack mean that olivine can replace silica sand as a foundry molding sand used for aluminum, brass, bronze, manganese steel, gray iron, and alloy steel. When casting manganese steel and other high-value alloys and copper and aluminum alloys, olivine sand produces a clean surface requiring minimal finishing. Additional benefits include the basicity of olivine, which enhances the bentonite bonding properties, thus reducing clay demand and its low and uniform expansion rate, which eliminates the need for cushioning agents and thus allows recycling. Its angular particle shape tends to use up to 50% more resin for binding compared with rounder silica sand.

Olivine has extremely high heat-retention properties and is used in the brick cores of heat-storage units.

Nonmetallurgical Uses

Olivine's properties of less than 1% free silica, a moderately high Mohs hardness of 6.5 to 7.0, a specific gravity of 3.3, a conchoidal fracture yielding an angular grain shape, and a light-colored dust allow it to be used as a loose-grain airblast abrasive, filtration media, and a weighting agent in concrete oil-production platforms. Olivine may replace silica sand as an airblast abrasive because of the reduced risk of silicosis used in repairing and maintaining ships, railcars, trucks and automobiles, and aircraft and maintaining structural steel such as bridges, oil rigs, boilers, storage tanks, and pipelines.

As a fertilizer and soil amendment, olivine contributes magnesia and iron as nutrients to the soil.

The light color of the dust also allows olivine to be used as a filler in specialty paints, asphalt, mastics, and roofing tile formulations. As a local rock, olivine can be crushed and used as an aggregate used in construction and concrete. Rock wool manufactured from olivine is being marketed in Europe as environmentally

friendly (or perhaps “green,” because the very name is derived from the Latin *oliva*, meaning *olive*, alluding to its olive green color). Night storage heaters have electric elements that heat up blocks of dense material such as olivine with a high specific heat capacity and cased in layers of insulation so that the heat escapes slowly.

Future Uses of Olivine

Olivine is a candidate for sequestering CO₂ emissions generated from burning fossil fuels. The concept of mineral sequestration involves the reaction of CO₂ with minerals to form geologically stable carbonates, i.e., mineral carbonation. One example would be to activate or pretreat the serpentine and olivine, which is placed in a solution of water, NaCl, and sodium bicarbonate to react with CO₂ at a high temperature. This method allows for 80% carbonation in less than an hour and forms magnesite (MgCO₃), silica (SiO₂), and water, which acts as the harmless storage unit. In principle, 1 t of olivine can dispose of approximately 0.67 t of CO₂ in an exothermic reaction that releases 90 kJ/mol.

1. $(\text{Mg, Ca})_x\text{Si}_y\text{O}_x + 2y + z\text{H}_2\text{O} + x\text{CO}_2 \rightarrow x(\text{Mg, Ca})\text{CO}_3 + y\text{SiO}_2 + z\text{H}_2\text{O}$
2. $\frac{1}{3} \text{Mg}_3\text{Si}_2\text{O}_5(\text{OH})_4 + \text{CO}_2 \rightarrow \text{MgCO}_3 + \frac{2}{3} \text{SiO}_2 + \frac{2}{3} \text{H}_2\text{O} + 64 \text{ kJ/mol}$
3. $\frac{1}{2} \text{Mg}_2\text{SiO}_4 + \text{CO}_2 \rightarrow \text{MgCO}_3 + \frac{1}{2} \text{SiO}_2 + 90 \text{ kJ/mol}$

The current pretreatment methods of heating or fine grinding are too energy intensive for practical use. Consequently, groups such as the Arizona State University (ASU) Carbon Sequestration Research Team (which is a member of the CO₂ Mineral Sequestration Working Group that is managed by the Fossil Fuels Division of the U.S. Department of Energy), are examining alternative methods.

Specifications

Typically, olivine contains 45% to 51% MgO plus 40% to 43% SiO₂; 7% to 8% Fe₂O₃; 0.2% to 0.8% CaO; and 1.8% to 2% Al₂O₃ + TiO₂, MnO, Cr₂O₃, NiO, and CoO. LOI is critical because this indicates the presence of hydrated minerals such as chlorite and serpentine. Table 2 gives the chemical analysis of some commercial olivine products. Sizes range from lump or aggregate (10 to 45 mm) to sand, to flour (–200 or –325 mesh).

Blast furnace-grade lump (10 to 40 mm) is for direct feed to the blast furnace and 0 to 6 mm or 0 to 3 mm to the sinter stream with an average MgO content of 47% to 48%. Foundry-grade olivine is mainly American Foundry Society (AFS) 20, 30, 60, 90, 120, and flour; for brass, bronze, and aluminum, it is AFS 100, 140, and 180. Filler grade runs 0 to 0.8 mm and 0 to 0.02 mm and fertilizer grade runs <0.1 mm.

Table 3 gives sizing from Italy as an example.

ECONOMIC FACTORS

Environment, Safety, and Health

One important attribute cited for olivine for use as a foundry sand or airblast abrasive is its low free-silica content. Any mineral product with a crystalline silica content of 0.1% or more, however, is generally regulated under U.S. Occupational Safety and Health Administration (OSHA) Hazard Communication Standards or similar standards, so they require a cancer warning label.

Substitutes and Recycling

Olivine competes with several minerals in several markets:

- As a slag conditioner against dolomite
- As a magnesia source (45% to 51% MgO) against magnesite (47.8% MgO) and dolomite (20% MgO)
- In abrasives against specular hematite, garnet, silica sand, and slag
- In fertilizers against dolomite, caustic magnesia, and magnesium sulfate

Theoretically, as an airblast abrasive, spent olivine can be recovered, cleaned, resized, and reused to offset the higher initial costs compared with silica sand or slags. In practice, not much olivine is recycled, and the higher price is thus justified by OSHA considerations and reduced liability. Reclaiming mold and core sands in foundries has increased because of escalating purchasing and disposal costs.

Future Trends

The iron and steel and metal foundry industries largely influence demand for olivine, and they in turn depend on consumer durable-goods sales and construction activity, both of which are tied to gross domestic product (GDP) and population growth. Iron and steel production tends to be strong during periods of economic expansion and slows down in line with the economy. In addition, demand for foundry sand has been reduced by the advent of continuous casting in the steel industry. On the other hand, consumption as an airblast abrasive and a foundry sand may be encouraged by cost competitiveness as well as OSHA regulations that discourage the use of silica sand (and chromite in foundries). Nevertheless, the limited sources of production, wide range of competitive materials, and relatively low selling price restrict olivine to local or regional markets, most notably in Scandinavia and Japan. Access to low-cost transportation is critical and is the main reason why Norway has been a successful exporter and producer.

Prices

Delivered prices for olivine depend on quality, packaging, and freight charges, with the low end of the range at commodity-like levels. Prices (in US dollars) quoted in *Industrial Minerals* in 2005 for the United States are approximately as follows:

- Ex-works foundry: \$60 to 110/t (AFS 30 to 180, bulk), \$77 to 125/t (AFS 30 to 180, bags)
- Flour: \$117/t (bags)
- Aggregate: \$50 to 78/t (bulk)
- Europe CIF (cost, insurance, and freight), crushed, for sinter pellets, blast furnace: \$13 to 19/t (bulk)
- Dry graded, refractory aggregate, ex-works: \$72 to 80/t (bags)
- Foundry and blasting sand, ex-works: \$78 to 84/t (bags), \$65 to 84/t (bulk)

- Sand for tundish spray: \$100 to 110/t (bags)
- EBT taphole filler, dry, ex-works: \$85 to 95/t (bags)

Perlite

James M. Barker and Ken Santini

INTRODUCTION

The expanding properties of perlite have been known for almost 2,000 years (Allen 1992). Called perlstein in Germany in the 1800s (Evans 1993), perlite was originally identified by its vitreous, pearly luster and characteristic curved (onionskin texture) perlitic fractures (Breese and Barker 1994). Textures of perlite range from classical (onionskin) to granular (most common commercial type) to pumiceous (lower density). Defined as having 2 to 5 wt % combined water, perlite occurs worldwide in young, glassy, rhyolitic, high-silica volcanic rocks generally less than 60 million years old.

Modern perlite production began in 1946 in Superior, Arizona, and soon thereafter in New Mexico with a trade organization, the Perlite Institute, in place by 1949 (Allen 1992). Crushed and sized crude perlite expands or “pops” into anhydrous glass foam when heated quickly to plasticity at about 600° to 900°C while releasing steam from combined water. Very fine perlite is expanded into microspheres typically less than 100 µm in diameter.

Industry may refer to any volcanic rock that expands as “perlite.” This includes obsidian (<2 wt % water), bloated in Japan, and pitchstone (>5 wt % water), expanded in Eastern Europe. The low density and porous texture of expanded perlite plus its low thermal conductivity, high sound absorption, and chemical stability give it many valuable commercial properties, especially in the construction industry (Breese and Barker 1994).

GEOLOGY

Perlite is one of the natural volcanic glasses containing combined water. These include obsidian, perlite, pitchstone, and hydrated volcanic ash or “pumicite” (Breese and Barker 1994). Perlite (2 to 5 wt % water) is hydrated volcanic glass formed over a few million years or so by the chemical weathering of obsidian at or near the earth's surface. The obsidian precursor to perlite originally contains ~0.1 to 0.4 wt % water because lava is nearly anhydrous at surface or near-surface pressures as water is evolved rapidly from the melt (Fisher and Schmincke 1984).

The water in obsidian is increased by gradual diffusion of meteoric water or sometimes other waters, such as thermal spring, phreatic or connate, into the high-silica (~70% to 75% SiO₂) rhyolitic (acidic) glass. Reincorporation of magmatic water from microvesicles and voids is also possible soon after cooling. The tension developed by the volume increase caused by this hydration results in the arcuate or concentric fractures typical of onionskin

perlite. Alkali-rich obsidian is hygroscopic, so alteration to perlite is inevitable but moderated by climate and wettable surfaces within the perlite body (Chamberlin and Barker 1996). Thus, perlite is not a primary igneous rock, although remnants of the primary obsidian or rhyolite may remain.

Semiarid climates are more conducive to retaining hydrated volcanic glass because it is not removed by the intense chemical weathering in a humid climate with its rapid flushing of glass dissolution products (see Lorenz and Muller [1982] for a tropical perlite).

Perlite is often described as metastable over geologic time. Although technically true, the reaction takes billions of years in the absence of water. Volcanic and impact glasses on the moon are still pristine after 4 billion years (Carmichael 1979), suggesting that the idea of devitrification of perlite deposits should be put to rest for practical purposes (Chamberlin and Barker 1996). The primary form of glass in older rocks is perlite, often recrystallized, if glass is preserved at all (Fisher and Schmincke 1984). Perlite dated as Devonian (391.0 ± 3.8 Ma by ⁴⁰Ar/³⁹Ar) is known from Gaspé Peninsula, Quebec, Canada (M. Heizler, personal communication, Argon Lab, New Mexico Bureau of Geology and Mineral Resources). Other deposits are Jurassic or Cretaceous but most are Tertiary.

Extreme viscosity of high-silica lava favors formation of very-thick glassy chill zones on the lava surface. The eruptive history of the parent volcano determines the potential size of the perlite resource (Figure 1).

The best resource is the glassy top of a permeable (microvesicular) high-silica lava flow. Steep-sided high-silica lava domes typically are larger and more common than flows but yield less perlite because their complex, multi-vent cooling histories form interleaved mixtures of glass and rhyolite (Chamberlin and Barker 1996). Formation of perlite is a very complex process that requires a long chain of fundamental or essential events. If one event is omitted or is incomplete, no commercial perlite will form (Figure 2).

Because perlite textures are a continuum based on many interacting volcanic processes, they often do not fit nicely into classification “boxes.” Common textures of perlite used by industry are pumiceous (least dense), granular, and onionskin (most dense). Most commercial perlite mined is now granular or pumiceous.

Pumiceous perlite is at the margins of the deposit and is typified by frothy, open vesicles that can show flattening and distortion because of compression and flowage shear. Obsidian cores and

Figure 1. Diagrammatic cross sections of a small dome (A), lava flow (B), and large composite dome (C). The composite dome shows several overlapping volcanic events which complicate commercial production compared to a single lava flow or small dome.

Adapted from Ohle and Bates 1981; Chamberlin and Barker 1996.

Figure 2. A sequential list progressing from top to bottom showing fundamental and essential geologic processes in the formation of commercial perlite. Open links show where the chain is most likely to be broken.

perlitic fractures, if present, are generally restricted to dense vesicle wall junctions and may not be visible in outcrops. Pumiceous perlite is friable and may not core or mill well.

Granular perlite has a sugary texture and blocky fracture. Collapsed vesicles impart a silky luster to surfaces that are nearly parallel with flow banding. Well-developed perlitic fractures are rare. Granular perlite typically cores and mills well.

Onionskin has well-developed curved perlitic fractures, initially used to define perlite, and pearly-to-resinous luster. Widely spaced vesicles are present but are highly collapsed. Remnant obsidian nodules may be abundant as isolated grains or as pods of varying dimensions. The obsidian grains in the onionskin zone may be gradational or abrupt and can rapidly increase toward the interior of the unit or laterally into subzones in which hydration of the glass is incomplete. Although onionskin perlite mills and cores very well, it is a limited resource in most deposits.

OVERVIEW OF WORLD PERLITE DEPOSITS AND ACTIVITIES

References used in this section are Kuzvart (1984), Harben and Bates (1990), Breese and Barker (1994), Harben and Kuzvart (1997), Kendall (1999b), Roskill Information Services (2000, 2005), Barker et al. (2002), and Harben (2002), as well as U.S. Geological Survey (USGS) country reports, numerous *Industrial Minerals* articles, personal communications with companies, and site visits by the authors. Note that S&B Industrial Minerals, hereafter called S&B, is very active throughout the world. With 35 mines, plants, and distribution centers in 13 countries, S&B is the largest single supplier of crude perlite in the world.

Table 1 shows approximate world production through 2003, which averaged about 2.9 Mtpy from 1999 to 2003, increasing from a world total of about 2 Mt in 1995 (Coope 1997).

Although deposits of perlite are widespread worldwide, they often are not developed and are available only as market conditions allow. Examples include the El Rosario deposit, 1 of 18 in El Salvador (Lorenz and Muller 1982). Barker et al. (2002) list at least 100 deposits in North America alone. While perlite mining and associated expanding operations are discussed in this section, the numerous operations that only expand are not covered.

Algeria

Algeria is believed to have a producer near Maghnia (BGS 2005).

Argentina

Perlite deposits in Argentina are in the north in Salta Province and west-central in Mendoza Province. Production in the 1990s varied from 9.4 to 27.6 ktpy (Kendall 1999a), mostly for domestic use as filter aids and insulation (Roskill 2000, 2005; BGS 2003). Production was 19,725 kt in 2003 and has ranged from about 17 to 21 ktpy in the early 2000s (BGS 2005). In 1997, three companies (Granulterm y Cia., Perfiltra, and Minaclar) produced perlite (Kendall, 1999a).

Perfiltra of Buenos Aires was established in 1967 under the name of Silflo Argentina as a subsidiary of Johns Manville Corporation but is now an independent. It mines perlite (~76% SiO₂) from deposits in the Argentine Andes at San Antonio de los Cobres in Salta Province. The company processes crude perlite and expands at San Antonio de los Cobres, Banda del Río Salí, Tucumán Province, and Rosario, Santa Fe Province. Perfiltra produces expanded perlite for construction, cryogenic and pipe insulation, filtration, and horticulture. In 2004, it produced 8.5 kt for filtration and 2.5 kt for horticulture.

In the early 1980s, Multiquim began mining perlite at 3,900 m in Salta Province. Most of the perlite mined in the 1980s was exported, but in 2005 the majority is expanded at a plant in Rosario. Although the major end uses are agriculture and construction, some is used for stone-washing denim, cryogenic insulation, industrial absorbents, ambient temperature insulation, abrasives, and filtration.

Armenia

Armenia has three perlite deposits (72.60% to 74.84% SiO₂) that have been mined, with reported combined reserves of about 320 Mt (Troitsky, Petrov, and Grishae v 1998). A fourth deposit at Vorotan is very large but uneconomic because of lack of transportation.

Perlite occurs in Upper Tertiary to Quaternary volcanics that consist of basalt overlain by trachytic-rhyolitic flows. The upper part of the flows includes acidic rocks such as rhyolite, obsidian, and perlite (usually onionskin). The perlite displays a gradual transition to rhyolite and obsidian with textural differences resulting from variations in the cooling of the acidic lavas (Harben and Kuzvart 1997).

Table 1. World production of perlite, t

* na = not available.

The mined deposits are Aragats (mined by Grefco Minerals about 80 km from Yerevan), Dzhraber (mined by Amperlite), and Fontan-Dzhraber. In 1998, Dicalite Armenia (a subsidiary of Grefco Minerals) purchased Aragats and acquired large high-grade reserves, plus a mine and plant. Most production is supplied to the Dicalite plant in Belgium.

Total Armenian production reached 700 ktpy in the 1980s with exports to Russia and Western Europe. After Armenia left the Soviet Union, production and export of perlite declined. During the mid-1990s, there were no exports to Russia, but these resumed in 1997. Production of perlite fell to about 17 kt in 2001, then rebounded to about 17.6 kt in 2003 (BGS 2005).

Australia

Minor production of perlite in Australia occurred as early as the 1970s (Allen 1992). Since 1990, production has remained below 10 ktpy and in 2003 was 9,440 kt (BGS 2005). Perlite is produced in Queensland at Numinbah Valley, Nychum, and Nerang.

At Numinbah, Australian Perlite (a subsidiary of Solvay Interlox) produced approximately 4 kt in early 2005. The crude perlite is trucked to Sydney for expansion.

The Nychum deposit, which may contain a 700-Mt resource, is now produced by Chillagoe Perlite (formerly James Meyer) about 50 km northwest of Chillagoe, feeding a plant west of Cairns.

Fernz Minerals (part of Orica Chemicals) mines about 5 ktpy at Nerang and expands in Banksmeadow, New South Wales.

Perlite deposits in New South Wales are on the southern margin of the Nightcap range. Deposits at Port Stephens, Stroud, and Gloucester are less than 2 m thick.

Bulgaria

Perlite (~73% SiO₂) was discovered in 1921 at Broken Mountain near Jebel about 25 km southwest of Kardjali and at Svetoslav near Cold Well Lake (Petrov 1994). The perlite deposits occur in acidic volcanics of Oligocene age (Petrov 1994). Both sites were evaluated during the 1950s, and production of perlite commenced in 1960. Since 1998, Bulgarian production has ranged from 10 to 17 ktpy, with 16.8 kt in 2003 (BGS 2005).

Bentonite AD is the only producer in Bulgaria and mines the Broken Mountain deposit. Proven reserves are about 800 kt. Perlite from the mine is transported about 12 km to a 70-ktpy plant. Processed perlite is supplied for glass manufacture and to the construction industry. In October 2003, S&B acquired a majority interest in Bentonite AD.

Canada

All perlite consumed in Canada is imported, whether in crude or expanded form. Nearly 95% of expanded perlite in Canada is utilized

in horticultural applications. The remainder is consumed in loose insulation and other uses. In 2003, U.S. and Greek exports of crude perlite to Canada were, respectively, 27,735 and 37,869 kt. Greek imports by S&B have exceeded those from the United States since 2001 (Roskill 2005). In British Columbia, 20 occurrences of perlite are known (White 1990, 1991).

In 1953 and the 1980s, the Francois mine near Burns Lake produced perlite (Giles and Poling 1991). Production from 1949 to 1953 was 1,597 t (BC Geological Survey 2005a) but the mine is not active at present. The abandoned Francois mine exploited a 2-m-thick bed of perlite that is in sharp contact above and below with rhyolite and typically exhibits onion-skin texture. Approximately 300 m north of Burns Lake a similar perlite bed, about 15 m thick, is exposed along an access road. The perlite at both locations is considered to be Eocene or Oligocene in age (Hora 1984).

Until 1987, Aurum Mines operated the Frenier mine about 60 km west of Clinton. Volcanic rocks at the site are correlated with the Eocene Kamloops Group and consist of rhyolitic tuff, rhyolite flow, perlite, and breccia. The flows are approximately 25 to 30 m thick and contain onion-skin perlite. Based on drilling, proven reserves are about 450 kt, and the inferred resource is 3.8 Mt, based on a specific gravity of 2.3 (BC Geological Survey 2005b). Frenier perlite was trucked about 400 km to Fraser for crushing and expansion. Production from 1983 to 1987 totalled 6.5 kt before the company filed for bankruptcy. In late 2003, BBF Resources shipped a 180-t bulk sample of Frenier perlite to a plant in the Vancouver area for pilot-plant testing to ascertain the recoveries of specific sizes of perlite. Subsequently, 40 t of horticultural perlite was shipped to one company for expansion tests, and another company tested a finer-grained product. BBF Resources dropped the project in 2004.

In Quebec, perlite on the Gaspé Peninsula is Devonian in age, making it one of the oldest explored perlite deposits in the world. Minor development occurred in the early 2000s, but the majority of the deposits near Mount Tuzo are not considered to be economically viable, although Perlite Canada may have mined some material during the mid-1990s (Roskill 2005).

Chile

In 2004, the Harborlite Chile mine and expansion plant in Santiago produced 8 kt of filter-aid and aggregate products. The filter aid is used domestically by the wine industry and is exported to wine producers in Mendoza, Argentina. Other deposits are near Concepción and at the Puelche Volcanic Field in the Andes of central Chile along the border with Argentina (Hildreth et al. 1999). A glassy, marginal zone of crumbly dark-gray perlite a few meters thick is exposed in patches around the edge of the otherwise devitrified rhyodacite body that has been glaciated.

China

Perlite occurs in more than 200 deposits in 17 provinces. Of these, 21 deposits have been explored in some detail. Listed here are perlite reserves in excess of 250 Mt (Lu 1998; O'Driscoll 1994c). China has more than 40 producers of crude perlite—all mines are open pit—and more than 300 producers of expanded perlite, mostly used for thermal insulation (O'Driscoll 1994a). The British Geological Survey reported that Chinese production of crude perlite in 2002 was 600 kt (BGS 2005), which may be understated because other Chinese statistics show 550 kt of exports above domestic consumption. The major recipients were South Korea (267 kt) and Japan (183 kt). The 2003 production of crude perlite in China was at least 750 kt.

The largest producer, at more than 300 ktpy, is Xinyang Shangtianti at Xinyang in Henan Province. The deposit (72% SiO₂) is in Cretaceous volcanic rocks as lenses (Lu 1998), which are in the

middle of the lava flows, underlain and overlain by rhyolite and bentonite. Most of the perlite lenses are 50 to 800 m long, 50 to 550 m wide, and 10 to 60 m thick.

S&B holds a 25% interest in Xinyang–Athenian (XAMCO) in Henan Province, one of China's largest operations. The remaining 75% ownership is the local government. Through Sino Hellenic Industrial Minerals Co. (SHIMCO), S&B operates a 150-ktpy facility producing crude perlite and expanded products. SHIMCO's major markets are China, South Korea, Taiwan, and Japan.

Commonwealth of Independent States

Perlite occurs at 21 deposits in seven former Soviet republics. Perlite production is conducted in Armenia, Ukraine, Russia, and Georgia, discussed in separate sections. Deposits are also found in Kazakhstan (Semeitau deposit), Azerbaijan (Kechaldag deposit), and Tajikistan (Tashkesken deposit), although no production is reported (Troitsky, Petrov, and Grishaev 1998).

Georgia

JSC Perlite mines the Paravand deposit (Troitsky, Petrov, and Grishaev 1998) that occurs in volcanic flows 20 to 195 m thick, associated with obsidian and rhyolite (Harben and Kuzvart 1997). From 1997 to 2003, production was about 5 ktpy (BGS 2003, 2005). Reserves are 30 Mt, of which approximately 2.5 Mt are suitable for filter aids.

Greece

Perlite deposits are found in mainland Greece at Trace and on several islands, including Milos, Kos, Yali, Chios, Kimolos, Lesvos, and Nissiros (Coope and Manos 1986; Hatjilazaridou, Chalkiopoulou, and Grossou-Valta 1998). Since 1997, crude-perlite production has ranged from about 695 to 850 ktpy (BGS 2003, 2005). Exports have been mainly to Canada, Germany, Israel, Italy, Netherlands, Spain, the United States, and a few others.

S&B mines perlite at two locations on the island of Milos: Trachylas (74.4% SiO₂) in the north and Provatas (74.71% SiO₂) in the south. Milos Island is part of a volcanic arch extending from the Attica region near Athens to the west coast of Turkey. Late Pliocene to Late Pleistocene acidic volcanism produced tuff, pumice, tuffite, and ignimbrites, along with domes and lava flows of andesite, dacite, and rhyolite. The last activity produced rocks weathered to perlite, presently exploited by S&B (Harben and Kuzvart 1997).

The Trachylas perlite is harder, and Provatas is softer. Of the 1,069 Mt estimated in 1991 for Milos reserves, approximately 17% are at Trachylas, and about 83% are at Provatas. Perlite at both locations is mined from open pits to feed a plant at Tsigrado (upgraded in 2003). Crude perlite is trucked to the processing plant at Voudhia Bay for further sizing to –3 mm, followed by drying and screening prior to storage in silos to await final shipment. The capacity of the S&B processing plant on Milos is about 650 ktpy. Most of the perlite produced is exported, although some is shipped to an expansion plant at Ritsona, which is 90 km north of Athens. Bulk shipments of 8 to 15 kt are destined for continental Europe, and 25-kt shipments for North America. Perlite products in containers go to the Far East and for special cryogenic projects elsewhere. In 2003, expanded perlite from S&B Greek and Spanish operations amounted to 240,000 m³.

Perlite sales from S&B are supported by “just-in-time” warehouses in China, Europe, and North America. Just-in-time refers to a process where suppliers deliver product to the warehouse only when it is needed, avoiding the necessity of storing large amounts of inventory. In 2003, four new just-in-time warehouses were opened in Central Europe and one in the United States.

In the mid-2000s, Greek exports of crude perlite increased from 462 to 650 ktpy worldwide, because of increased market penetration in North America. At the same time, European sales have decreased, mainly because of a loss of 100 ktpy in construction products in Germany.

Armstrong Industries, a producer of ceiling tiles, is S&B's major customer in the United States. Its plants in Mobile, Alabama, and Pensacola, Florida, began taking perlite in 2003 from a warehouse in Mobile.

Aegean Perlite has mined on the northeast side of Yali, between the islands of Kos and Nissiros in the southeast Aegean Sea. Capacity of the open pit is 250 ktpy; perlite is air-dried before crushing and sizing. Production by Aegean Perlite commenced in 2002, when about 80 kt was produced from Yali.

Bouras produces approximately 30 ktpy of perlite from Milos, mainly for the German market, and also has operations on Kos.

Hungary

Hungarian perlite deposits are in the Tokaj Mountains of Zemplén Province at Pálháza (close to the Slovakian border), Erdőbénye, Abúszántó, Telkibánya, and Mádl (Shackley 1990; Roskill 2005). They occur in a 2,000-m section of Tertiary andesitic volcanics (Shackley 1990; Harben and Kuzvart 1997). In a 2000 estimate, reserves were about 2.8 Mt. Production has ranged from approximately 72 to about 175 ktpy since 1998 (BGS 2003, 2005). Approximately 30% of production in 2002 was exported mainly to Austria, Germany, and Poland.

Perlit-92 Kft (Kendall 1994), the sole producer in Hungary, is owned by Duna-Dráva Cement és Mészmuvek Kft, which is part of the German Heidelberger Zement group. Perlit-92 Kft has mined perlite (68% to 75% SiO₂) at the Pálháza deposit, first mentioned in the 18th century, since the mid-1950s and controls a deposit at the village of Bózsza (5 km from Pálháza). The grayish-black ore is in a distinctive columnar form (Kendall 1994). Mining is by drilling and blasting in an open pit (2.4-Mt resource) and trucked to a nearby 200-ktpy plant. Mine-run perlite is crushed, dried in a rotary kiln, and further sized before being screened into at least 15 grades and stored in silos.

Iceland

Iceland has several perlite deposits with commercial potential. A deposit in the Prestahnúki Mountains, about 100 km from Reykjavík, is reported to contain 48 Mt of perlite. The deposit originated in the Pleistocene by a rhyolite eruption under a glacier (Harben and Kuzvart 1997). Although the deposit is 50 km from the nearest harbor, access is easy only during the summer. Limited production of perlite may have occurred from this deposit, but no current information is available. Another perlite deposit is at Seydisfjörður on the east coast and close to a possible deep-water anchorage.

India

Perlite deposits are in Gujarat State, in parts of the Saurashtra, Kutch, Kheda, Sabarkantha, and Vadodra districts. Past production was by Raj Minerals, which may not be operating in 2005. Production has been very small and highly variable since 1990, ranging from 15 to 452 tpy (BGS 2003, 2005).

Iran

Perlite occurs at Khalkhal in Ardebil Province. Production, probably by Roudsaz in Tehran, has ranged from about 15 kt to about 28 kt in recent years (BGS 2003, 2005). At least 11 deposits are listed in the National Geoscience Database of Iran (www.ngdir.ir/MiningInfo/

[OrbadyInfo.asp](#)) in the states of Azarbaijan-e-Sharqi: near Miyaneh [6 deposits], Salmas [1], and Tabriz [1], Ardebil (Nir [1]), and Tehran (Damavand [2]).

Italy

Since the mid-1990s, perlite production has been about 60 ktpy (BGS 2003, 2005), and domestic consumption is estimated to be 70 to 80 ktpy. Exports of crude perlite are to France, Germany, United Kingdom, and others.

Western Sardinia contains the largest perlite deposits in Italy and is the only production site. The perlite occurs in Tertiary acidic volcanic rocks of the Mount Arci Complex on the northeast side of the Campidano Rift Valley at Morgongiori and Pugifiari. Perlite textures range from pumiceous to granular to onion-skin. Silica content varies from ~68% to ~73% (Jebson and Allen 1986). Ceca Italiana mines at Pugifiari, with most of the perlite being used by its plants at Pioltello (near Milan) and Sale rno. Sarda Perlite (51% S&B) mines near Morgongiori, and its 120-ktpy processing plant is at Torre Grande near the port of Oristano.

In the 1980s, VIC Italiana ceased mining on the island of Ponza, west of Naples.

Japan

Perlite is produced in the Kushiro, Kitakata, Tomioka, Yamaguchi, and Chiba regions. Recent annual production has ranged from 240 (2002) to 290 ktpy since the late 1980s (O'Driscoll 1994b; BGS 2003, 2005). More than 20 mines extract perlite from Miocene–Quaternary acidic volcanic rocks (Harben and Kuzvart 1997). Approximately 200 ktpy are imported, mainly from China, and about 15 ktpy of domestically produced perlite is exported, mainly to South Korea.

With approximately 45% of total production, Mitsui Mining and Smelting (formed in 1990) is the largest producer. Its mines are at Mikata (Hyogo Prefecture), Kitakata (Fukushima Prefecture), and Sagayamauchi (Sagami Prefecture). The Kitakata mine is Mitsui's largest, at approximately 50% of annual production, with Mikata producing 20% and Sagayamauchi 30%. Mitsui's expansion plants are at Funabashi (Chiba Prefecture), Kitakata and Omuta (Saga Prefecture), and Osaka (Osaka Prefecture).

Perlite is also mined, processed, and expanded by Toho Perlite at Wadatoge, Nagano Prefecture; by Nippon Perlite at Tsuruoka, Yamagata Prefecture; and by Shinano Perlite at Shinano, Nagano Prefecture.

Macedonia

Perlite is found in Tertiary volcanics close to the border with Greece. The major area is at Nižde Mountain where perlite is associated with Pliocene latite in the Gradesnica deposit. Development was active in the late 1990s with production expected to reach 80 ktpy (Harben and Kuzvart 1997), but none occurred.

Mexico

Mexican production has ranged from about 50 ktpy to about 97 ktpy since 1997 (BGS 2003, 2005). Major production in Mexico by Termolita and Compañía Minera Oriental totaled about 35 kt in 2003. This reflects a sharp decline in mine production resulting from a decrease in the market in Mexico and a reduction of unsalable perlite grades because of efficiency improvements at the mines (Barker, Santini, and Alatorre 2004). Sonora and Chihuahua also have minor production.

Termolita started operations in 1970, and production in 2005 was about 25 kt, mostly for domestic use. Some perlite is exported to the United States. The Leticia mine, 25 km west of the city of

Durango, Durango state, in north-central Mexico, supplies about 25 ktpy of crude perlite to an expansion plant 600 km east in Monterrey, Nuevo Leon. Proven reserves are large and mainly onionskin. Termolita has four expanders in operation (two horizontal, one vertical, and one portable for cryogenic) with a yearly capacity of 1.32 million bags containing 0.125 m^3 of expanded perlite.

Grefco Minerals owns 49% of Cia Minera Oriental and Dicalite de México. Cia Minera Oriental extracts perlite from the 35-ktpy open-pit Dimesa mine at Oriental (Puebla), approximately 24 km northeast of Mexico City and supplies Dicalite de México's three expanders (two horizontal [800 kg/hr] and one vertical [2,500 kg/hr]) in Mexico City. It also expands perlite at the mine to supply Dicalite de México, which ships to all states in Mexico and to Latin America.

Industrias de Perlita mines at El Prieto for its expansion plant in Ciudad Juárez y Asencion, Chihuahua. Aislantes del Pacifico mines at Ciudad Obregon, Sonora.

Morocco

The Tiedennit perlite deposit mined by Perlite Roche is east of Tangier in Nador Province. Reserves are about 38 Mt, of which 2 Mt are proven. The Moroccan government, via the Bureau du Recherche et de Participations Minières, owns 20% of Perlite Roche. The remaining 80% is owned by Roche Invest (Moroccan Canadian), which can process 20 ktpy. The main market for Perlite Roche is acidity control during phosphate production. An associate company, Roche Perlite, began expanding in 2001 using an Incon furnace at Berrechid near Casablanca.

Mozambique

Mozambique may currently produce perlite near Muguene, (west of Maputo) in the Lebombo Mountains that extend into South Africa (BGS 2005). The perlite is associated with obsidian and bentonite in the Karoo Supergroup. At Muguene South, the reserves of perlite are 100 kt (proven) and 400 kt (probable). At Muguene North, the reserves are 250 kt (proven) and 1 Mt (probable). The bulk density from Muguene is 0.109 g/cm^3 (6.84 lb/ft^3). A small furnace with small output operated in the 1960s (Cilek 1989).

New Zealand

Perlite occurs in Quaternary rhyolitic domes and flows (Christie et al. 2000). Large deposits occur in the Rotorua-Taupo Volcanic Zone of North Island. Other deposits are on Great Barrier Island northeast of Auckland and at Coromandel. Deposits at Great Barrier Island and Paku Island (both North Island) are Pliocene; at Kinleith and Atiamuri (North Island), Pleistocene-Holocene; and at Gebbies Pass (Banks Peninsula, South Island), Miocene (Harben and Kuzvart 1997).

Production has ranged from about 1.8 to 3.3 ktpy in recent years with minor production as early as the 1970s (Allen 1992). Industrial Processors of Waitakere, West Auckland, mines about 2 ktpy at Atiamuri, north of Lake Taupo, southwest of Rotorua, and 100 km southeast of Hamilton. The perlite is in a small glassy rhyolite dome on the margin of a much larger lithic rhyolite dome within the Taupo Volcanic Zone. The perlite is crushed and screened at the Fulton Hogan Atiamuri sand-processing plant. Material expanded in Auckland is well suited to cryogenic insulation and filter aids.

Peru

Cia Minera Agregados Calcareos of Lima produced perlite in the past but ceased in the 1990s.

Philippines

Perlite deposits are found in Legaspi City, Bagumbagan, Bicol, and the Calayan Islands. Philippine production has ranged from about 4.6 ktpy to about 61 ktpy since 1997 (BGS 2005) with minor production as early as the 1970s (Allen 1992). Exports are mainly to South Korea and Taiwan and less to Thailand and other countries. Philippine exports of crude perlite ranged from 5 to 8 ktpy in the early 2000s.

Induplex is a private company, sold by Dicaperl in the mid-1990s, that retains rights to use the Dicalite trademark. Induplex mines perlite at Legaspi and has a processing plant close to the mine. Its Cavite plant, about 8 hr by road from Legaspi, produces expanded perlite, at up to 15 ktpy.

In 1985, United Perlite acquired Trinity Lodge Mining, established in 1968. United Perlite mines in the Bicol region about 600 km south of Manila and markets products through UBS Marketing, concentrating on filter aids for sugar, coconut oil, and pineapple processing.

Russia

Perlite occurs in Buryatia, on the Kamchatka Peninsula, in Pribalkalie, near Baikalsk, at Pri morskoy krai, Magadan oblast, Chita oblast, Khabarovsk krai, and the Kuril Islands. Reserves in Buryatia are 30 Mt. JSC Perlite of Zaigraevsky raion mines the Mukhor-Talinskoe deposit in Buryatia, and JSC Kamchatskstroimaterialy mines the Nachikinskoe deposit on the Kamchatka Peninsula. Perlite production is 45 ktpy (BGS 2005), including 5 ktpy exported mainly to Japan.

At the Mukhor-Talinskoe deposit, Cretaceous volcanics resembling a highly eroded cone have a central core of rhyolite surrounded by glassy rocks. Weathering has produced secondary minerals such as zeolites, cristobalite, and monmorillonite. The Nachikinskoe deposit occurs in the center of a ring structure, probably an old extrusive caldera of an andesite volcano. Perlite in the lower zone is 2.5 to 10 m thick; the upper part is largely composed of rhyolite and obsidian (Harben and Kuzvart 1997).

Saudi Arabia

Onionskin and granular perlite occur at Harrat Shama (Tafil) and Jabal Shama on the Red Sea coast, about 100 km south-southeast of Jiddah (Laurent 1993), in Tertiary rhyolite flows and breccias (Jeffrey 2002) of the Miocene Liyyah Formation (Laurent 1993). The perlite has been explored and tested, with mixed results, but has not been produced. Perlite is also found at Jabal al Abyad, 130 km north of Al Madinah, associated with acidic volcanic centers. Preliminary testing yielded noncommercial results.

Slovakia

Perlite occurs in Tertiary volcanic rocks (Harben and Kuzvart 1997) at Lehôtka pod Brehmi, Jastrabá, Mala Bará, and Byšča. Total reserves are 30.5 Mt and extend into Hungary. Production ranged from about 19 kt in 1999 to about 15 kt in 2004 (BGS 2005).

Kerko-Perlit mines all of Slovakia's perlite at Lehôtka pod Brehmi, which is processed nearby. Approximately 80% is exported, mainly to the Czech Republic.

South Africa

Perlite (71.72% to 72.36% SiO_2) occurs in the Lebombo Mountain Range, Natal, in Jurassic acidic volcanic rocks as lenses and layers, and has a granular texture (Harben and Kuzvart 1997). These deposits occur near the Mkuze Game Reserve in KwaZulu-Natal around Nxwala Hill along the border with Mozambique. Drilled in

the mid-1970s, proven reserves of 3 Mt were shown in irregular lenses (Strydom 1998). Prately Perlite Mining, sole producer in South Africa, selectively mines Nxwala (Griffiths 1989). The perlite is crushed, dried, classified, blended, and expanded at its Krugersdorp plant for horticulture and construction. Annual production from this resource is approximately 1.2 kt or less (Skillen 1995). In addition, about 10 ktpy of crude perlite is imported from Turkey.

Thailand

Perlite deposits are found in Lopburi Province. Thai production has ranged from about 550 tpy to about 9.9 ktpy since 1997. About 7.6 kt was produced in 2004 (BGS 2005).

Turkey

Turkey has more than half the world's perlite reserves (Houssa 1999). Evaluations of the perlite place the resource at as much as 4,000 Mt (Ozgur 1997). The Turkish government calculated perlite reserves at 5.7 Mt. An estimated 2.8 Mt of this reserve are in eastern Turkey near Erzurum and Karas and extending into Armenia. Other deposits are in western Turkey near Ankara, Izmir, Manisa, Dikili, Bergama, and Çanakkale.

Reported production of crude perlite varies widely by agency. Since 1997, production has been increasing and ranges from about 105 ktpy to about 250 ktpy and in 2004 was about 137 kt (BGS 2003, 2005). Domestic consumption is low (20 kt in 1996; Ozgur 1997), so approximately 75 % is exported to Western Europe including Italy, Belgium, France, Spain, and the United Kingdom. Other importing countries include Brazil, India, Russia, Saudi Arabia, South Africa, and South Korea. After starting in 1961, total exports ranged from about 100 ktpy to 200 ktpy in the early 2000s.

Turkish perlite sells for approximately 40% less than Greek perlite because Turkish exports to Western Europe are mainly for filter aids that sell for less than construction and horticultural perlite. Producers include Eti Mine Works, Harborlite Aegean Endustri, S&B, Per&Tas, and IPM Group.

Eti Mine Works consists of two state-owned mines producing perlite (72 % to 76% SiO₂) at Menderes (Mezarkaya mine) and Manisa (Karagöl II mine). These operations feed a 145-ktpy crushing and screening plant at Izmir, which also has the ability to produce annually 130,000 m³ of expanded perlite and 2,500 m³ of micronized perlite.

Harborlite AS, formed in 1995 from Ege Endustri Mineralleri Sanayi AS, mines near Bergama, feeding a processing plant in Dikili that has an annual capacity of 100 kt. Much of the crude perlite is exported to affiliates in Europe.

IPM Perlit (IPM) mines perlite at Kocaköy, Deveboynu, Bademalan, Maruflar, Damsitepe, and Seleme, encompassing 8,000 ha containing approximately 25 Mt of reserves (*Industrial Minerals* 2004). In 1999, IPM formed Diperlit Filter Mining and Industry to produce and sell to domestic and international markets from an 80-ktpy processing plant at Yayıntaş, Bergama, in Izmir Province. Most production is for the Western European filter-aid market. While large shipments by IPM go through the port at Nemrut Bay, smaller bulk shipments are through Dikili with container/bagged shipments via the port at Izmir.

S&B has owned most of Pabalk Mining and Saba Madencilik since 1995. Pabalk mines near Biga in Çanakkale and supplies perlite to Saba Madencilik, which operates a 40-ktpy processing plant approximately 3 km from the port of Karabiga, where all processed perlite is exported.

Perlitas Istanbul Perlit Sanayi ve Ticaret mines about 40 ktpy at Bergama. Its processing plant at Bergama can produce 50 ktpy of crude perlite, mainly for filter-aids manufacture.

Per&Tas mines in Izmir.

Ukraine

The Shinoi-Varna deposit (72.98% SiO₂) near Zakarpattia is mined by JSC Beregovsky, the only commercial producer. Since the mid-1990s, production has been about 24.3 ktpy, far below capacity of about 340 kt. Three grades of crude perlite are produced. The finest grade is used in ceramic tiles, whereas coarser grades are used in construction and horticulture. Two undeveloped deposits in the same area are Arlovskoe and Fogoshskoe with reserves of 66 Mt and 28 Mt, respectively.

United Kingdom

Perlite occurs in northwest United Kingdom and on the Isle of Arran. Perlite deposits in Northern Ireland at Sandy Braes, County Antrim, have estimated reserves of 10 Mt. About 13.8 kt were produced between 1951 and 1968 by British Gypsum. Antrim Perlite evaluated this deposit in the mid-1990s and was issued a prospecting license in 1997. Progress has been hampered by lack of a local market.

The United Kingdom is a major importer of crude perlite, averaging approximately 65 ktpy in the early 2000s, mainly from Germany, Italy, Netherlands, and Turkey.

United States

Total U.S. production in 2004 was 510 kt, an increase after five consecutive years of decline (Table 2; Barker and Santini 2005). Recent extensive discussion of North American deposits can be found in Austin and Barker (1995, 1998), Chamberlin and Barker (1996), Kendall (1999b), and Barker et al. (2002).

Exports to Canada and the Pacific Rim partially offset imports. After a record 245 kt in 2003, imports from Greece to the Eastern and Gulf coasts of the United States declined about 22%. The market for Greek imports remains protected by high rail rates from western U.S. plants. Minor imports by Termolita from Mexico persist. In 2004, Noble Materials was sold to Grefco (Dicaperl), and in 2005, Basin Perlite was sold to Harborlite (World Minerals), and World Minerals was sold to Imerys.

Overall U.S. consumption declined about 6%, a decrease for the fifth consecutive year since 2000. Since 2000, consumption dropped about 18% mainly because of lower demand in construction (Bolen 2005). The average price of perlite in the United States declined about \$3.00—to \$35.22—in 2004.

End uses of expanded perlite, including microspheres, was construction, 62% (64% in 2003); horticultural aggregate, 13%;

Table 3. Estimated 2004 production of processed perlite sold by the four largest producers in the United States

Perlite Operation	Production,* 1,000 st	Production,† kt	Percentage of Total
Harborlite, No Agua, New Mexico	216	196.0	38
Harborlite, Superior, Arizona	50	45.5	9

U.S. total	560	510*	100

* Estimated.

† Calculated and rounded from estimates.

fillers, 10%; filter aids, 9%; and other, 6% (Bolen 2005). Crude perlite was produced by eight companies in seven western states operating 10 mines (Table 3). Sales remain strong for very coarse horticultural perlite (hort) or very fine perlite for microspheres.

Development of microspheres continues to meet customer demands in the 2000s for ever lower density and specific shapes or treatments. Worldwide microspheres production is by five U.S. companies: Harborlite (Utah), Therm-O-Rock West (Arizona), Therm-O-Rock East (Pennsylvania), Silbico (Illinois), and Dicaperl (Colorado, Nevada, and Oklahoma). Only Harborlite Utah and Dicaperl control their own sources of perlite.

Arizona

Middle Tertiary flow-banded rhyolite partly underlies low hills on the northern flank of Picketpost Mountain and a few miles to the east. Intercalated with the rhyolite is onion-skin perlite (~71% to 75% SiO₂) that locally exceeds ~200 m in total thickness (Welty and Spencer 1987; Austin and Barker 1995). The Harborlite mine is in Pinal County ~3 km southwest of the processing plant at Superior and includes the former Nord operations. Onionskin is mined from a 2- to 15-m bed that has a trace of pumiceous perlite and contains black obsidian (Harben and Kuzvart 1997). Production was 45 kt in 2004 and is particularly well suited for filter aids. About 98% is used "in-house" at Harborlite expansion plants and about 2% is used in aggregate.

California

American Perlite mines and processes perlite 11 km from Big Pine near Fish Springs in the Owens Valley, Inyo County. A Recent volcanic dome, ~65 m in height, is elongated east to west and capped by layered, vesicular pumiceous perlite (74.5% SiO₂) locally with dark-gray to black obsidian (Austin and Barker 1995).

Production in 1997 was about 36 kt of granular perlite from an ~25-m ore zone. About 75% to 80% was trucked to Southern California for lightweight aggregate in fiberboard and approximately 20% to 25% for horticultural purposes.

Idaho

During the late 1980s, National Perlite Products (Oglebay Norton) mined the Wrights Creek deposit, which is located approximately 40 km south of Pocatello, Idaho and contains about 10 Mt perlite (75% to 76% SiO₂), pumice, and rhyolite as part of a caldera com-

plex. A dacite plug underlies part of the perlite yielding near vertical dips (Austin and Barker 1995).

The crude perlite was expanded at Malad City, 40 km south of the mine, until 1994. Several owners subsequently tried to reopen the operation. During 2000, Idaho Minerals purchased perlite from other producers in an attempt to enter the perlite business using the Malad City plant while it evaluated the mine at Wrights Creek. This operation was inactive in 2005.

New Mexico

New Mexico continues to be the major producer in the United States with production at No Agua Peaks and Socorro. The Socorro deposit is mined by Dicaperl, and the operations at No Agua include mines and processing plants owned by Harborlite and Dicaperl. Both companies have additional processing and truck or rail loading facilities 37 km north in Antonito, Colorado.

The U.S. Gypsum mine at Grants had minor production throughout the 1990s (<10 ktpy). The granular perlite on the flank of East Grants Ridge consists of a domal complex of perlite, obsidian, and rhyolite flows (Weber and Austin 1982) about 3.3 million years old (Barker et al. 1989). The operation was put on the market in 2001 and due diligence was performed, but no sale was made. The plant was dismantled, the mill and mine were reclaimed, and the lease from the railroad was dropped in 2003.

The Dicaperl mine is about 5 km southwest of Socorro in Socorro County on the southeast flank of Socorro Mountain (part of a caldera complex). The Miocene volcanic glass hosting the granular perlite is about 7.85 million years old and is part of a high-silica (74.35% SiO₂), high-potassium rhyolite. The perlite, which is in a faulted dome, is at least 200 m thick in places, so reserves are substantial (Weber and Austin 1982; Austin and Barker 1995; Chamberlin and Barker 1996). Rippers and scrapers feed a conveyor belt to the processing plant for drying, grinding, air classifying, and storage in silos. Production of about 250 ktpy in the early 2000s dropped to 118 kt in 2004. Dicaperl produces 8 to 10 grades blended as needed to customer specifications and shipped by rail to in-house and customer expanders mainly for ceiling tile and horticulture.

The Dicaperl El Grande mine, part of the Nu-Alexite deposit, is on the western side of No Agua Peaks, a few miles north of Tres Piedras in Taos County. The deposit is a Pliocene (~4 million years old) glassy lava flow (75.97% SiO₂), weathered to granular perlite (Austin and Barker 1995; Chamberlin and Barker 1996). Obsidian is locally abundant. Mining is by ripping, scraping, and occasional blasting before the short transport to the plant. Mined perlite is passed over a grizzly and through a jaw crusher before entering a rotary dryer, followed by grinding and screening. Past output of this mine, which had been the third largest perlite mine in the United States, was about 180 ktpy. In 2004, when 5 kt was produced, Dicaperl put the El Grande mine at No Agua Peaks on standby for campaign mining. About 80% of past production was used in the construction market, about 10% for horticulture, and 10% mainly for at least seven grades of filter aids.

The Harborlite No Agua mine, approximately 3 km east of U.S. 285 and in the eastern No Agua Peaks adjacent to Dicaperl, was the largest perlite producer in the United States in 2004 (Table 3). This deposit was originally owned by the Schundler Company (a perlite and vermiculite processor in New Jersey) followed by Johns Manville until it came under the control of World Minerals, Inc. in 1991. The dissected rhyolitic dome (from one to four domes) (Naert 1974; Breese 1984; Whitson 1982; Chamberlin and Barker 1996) and flows are Pliocene (about 4 million years old) with locally abundant obsidian. Mining, in several open

pits over the years, is by ripping and occasional blasting of perlite, which is then moved by front-end loaders into trucks that haul it to the mill for drying, grinding, and classifying into seven grades, and then to silos for storage. Perlite is pulled from silos for blending or on-site expansion or to meet customer specifications and then discharged into pressure-differential railcars at Antonito. A small amount is trucked. Most is shipped to ceiling tile and construction end users or Harborlite expansion plants.

Many perlite deposits in New Mexico have been evaluated since the 1950s, but none has been mined for sustained periods. The Brushy Mountain pumiceous perlite deposit is about 16 km east-southeast of No Agua Peaks and was most recently mined by Silbrico until the early 1980s. The perlite is a vitrophyric breccia ~22 million years old (Oligocene/Miocene) with associated rhyolite flows (Weber and Austin 1982). The large amount of fine waste plus transport over gravel roads made this relatively remote operation unprofitable. Scharkan (1992) investigated three deposits at McDonald Ranch and Wallace Ranch, both of which have been drilled and tested, and at Schwartz. The Leitendorf Hills pitchstone, about 15 km south-southwest of Lordsburg (Weber 1963), is very large and was mined briefly in the early 1950s (Flege 1959), but the variability and high expanded density of the pitchstone have hindered development since.

Nevada

Nevada has large perlite resources, and several have been mined extensively. The largest past producer was the Hollinger mine near Pioche in Lincoln County. Perlite production in Nevada in 2002 was restricted to relatively small-scale mining of three deposits for niche markets.

The Tenacity mine of Wilkin Mining and Trucking, about 40 km west of Caliente in Lincoln County, is an open-pit operation that exploits a blue-gray onionskin perlite of Miocene age. The top of the mined interval has obsidian in irregular patches (Austin and Barker 1995). Wilkin operates a small expansion plant in Caliente, about 50 km east of the mine. Production has been as high as 3.6 ktpy, principally for the horticultural market in Southern California. In 2004, the company shipped about 1.6 kt.

At the Eagle-Picher 6.6-ktpy plant, about 11 km northeast of Lovelock at the Eagle-Picher Colorado diatomite operation in Pershing County, production in 2004 was ~4 kt. The screening and expansion plant came online in 1994 with one furnace feeding captive filter-aid (12 grades) operations. Crude perlite is from the Popcorn mine in Churchill County, 55 km south of Fallon and about 130 km south of Lovelock, with reserves estimated to be 1.4 Mt. Granaria Holdings of the Netherlands is the controlling shareholder of Eagle-Picher, which was for sale in 2005.

In 2001, Noble Materials began mining from a deposit a few kilometers east of the Popcorn mine for microspheres production in Fallon. The microspheres were sold in sizes that averaged between 30 and 70 μm . In 2002, the company ceased mining in Nevada and switched to Cornerstone perlite from Oregon (USGS 2002a) and Harborlite perlite from New Mexico. The Noble operations in Nevada and Oklahoma were sold to Dicaperl in 2004.

Oregon

Cornerstone Industrial Minerals, part of Seven Peaks Mining, runs the Tucker Hill perlite mine about 55 km northwest of Lakeview in Lake County. The perlite varies from onionskin (minor) to granular, the preferred ore with less obsidian. Proven reserves are 4.9 Mt, and indicated resources are more than 30 Mt. The perlite is mined using blasting in an open pit and crushed to -1.25 cm . It is trucked to the processing plant at Lakeview where it is further crushed, dried, and

screened to produce 11 standard plus custom grades of crude perlite stored in silos for blending, if required. Shipments are mainly by rail or truck (Speltz 1998) to expanders near Portland, principally on contract to Armstrong World Industries in St. Helens. The 2005 production of Cornerstone was ~112.5 kt, mostly for horticulture but also for ceiling tile and industrial insulation. About 75% of the sales were to the western United States, western Canada, and the Pacific Rim; the rest was sold to customers mainly in the eastern United States and eastern Canada (Barker, Santini, and Alatorre 2004).

Supreme Perlite, established in 1954, periodically mines at Dooley Mountain in Baker County, east of Portland. Processed perlite is shipped to its expansion plant in Portland and to other end users. Supreme sells several grades to the construction and horticultural markets. In the past, most perlite that Supreme expanded in Portland came from No Agua, New Mexico.

Utah

The crude perlite and microspheres plants of Basin Perlite are at Milford, Utah, about half way between Las Vegas and Salt Lake City, on the main line of the Union Pacific Railroad. Harborlite Utah produces crude perlite products (horticulture, construction) and microspheres. It also supplies microspheres feed to both Therm-O-Rock East (New Eagle, Pennsylvania) and Therm-O-Rock West (Chandler, Arizona); the latter produces microspheres for Harborlite Utah through a tolling agreement. The microspheres are shipped to Harborlite Utah's joint-compound customers in Arizona, Malaysia, and Mexico, which include U.S. Gypsum, the world's largest producer of joint-compound (from the Harborlite Utah, Therm-O-Rock West, and Therm-O-Rock East plants). Therm-O-Rock East produces microspheres for customers in the eastern United States and eastern Canada.

The Basin deposit, in the Mineral Mountains about 18 km northeast of Milford (USGS 2002b), occurs in the Quaternary Bailey Ridge Flow, which is subdivided into three lithologic units: lower rhyolite; middle rhyolite and obsidian; and upper obsidian and perlite, which hosts the Basin open pits (now dormant). Perlite is up to 27 m thick, and total reserves or resources are approximately 25 Mt (Santini 2003). Mining was by contract as campaigns (14 to 36 kt) in open pits by ripping with a bulldozer or excavator, followed by crushing and screening. The 23-tph plant had a capacity of 91 ktpy, where drying and crushing produced 10 standard sizes stored in silos for blending, if needed; Basin typically blended ~20% to 30%. Basin shipped in bulk and in various packaging, including 910-kg supersacks and 151-L barrels for foundries. Harborlite Utah now processes perlite from the Black Rock Desert 65 km to the north in the former Basin plant.

Fine perlite for microspheres is pneumatically conveyed from the perlite plant to the microspheres plant. The perlite is roller-milled and air-classified before discharging to a vertical expansion furnace. Uncoated microspheres are produced and shipped in bulk or in 227-kg supersacks. Basin also produced coated microspheres as needed.

EXPLORATION

Deposits of perlite occur commonly throughout the world, and geologically the outlook is excellent for discovery and development of new resources. The competitive pressure exerted by existing producers within market areas will impair the ability of new sources to supply the same markets and end users. This is especially true in the United States.

Fundamental strategy for the exploration for perlite requires an integrated approach incorporating the recognition of geologic

occurrence and lithologic and temporal modeling. Perlite is usually associated with Tertiary to Quaternary high-silica volcanic rocks and flows/domes, which provide general parameters to guide regional reconnaissance for new resources. Rhyolitic complexes of Oligocene to Middle Quaternary age have proven to be successful target areas for initial field reconnaissance. The glasses within this age range are old enough to have hydrated extensively and are young enough to have escaped extensive erosion. More recent glasses are likely to be incompletely hydrated and to have less commercial potential as sources for high-quality perlite. The hydrated glass selvages of flows and extrusive domes are often extensive and can be easily mined using low-cost open-pit methods, making this occurrence type an attractive target for exploration. The perlitic tuffs and breccias often associated with domes and flows offer additional resources.

The study of many deposits provides useful lithologic and textural models that have been developed for exploration and evaluation of deposits. Models help guide the placement (and termination) of drill holes and mine planning. Though the presence and the development of textures and zonation are variable among deposits, the features exhibited at the No Agua deposit in New Mexico are commonly observed in flow/dome occurrences throughout the world. Although no single model can be applied to all occurrences (Chamberlin and Barker 1996), the rock types, textures, and zonation as described at No Agua provide a useful basis for geologic mapping and for the uniform comparative description and interpretation of deposits.

Traditional methods used for exploration of perlite deposits include detailed mapping to identify source vents and flows, core drilling, and trenching. Detailed mapping is employed to delineate basic rock types, perlite textures, and contaminants such as clay, caliche, rhyolite, and obsidian. Mapping and modeling can be used in conjunction with geophysical techniques for the prediction of trends and the location of the concealed portions of perlite bodies. Core drilling and trenching are used to assess continuity and quality of perlite. Optimum spacing and placement of drill holes is based on the variability of lithology and quality within individual deposits. The core diameter must be large enough to ensure high core recovery and to provide sufficient samples for evaluation. If perlite quality is uniform and geology is well known, cuttings from percussion, rotary, or reverse-circulation drilling can be used instead of core.

MINING

Throughout most of the world, the lower cost of surface mining relative to underground mining drives producers to use open-pit methods. Most perlite mines use either ripping or blasting, or both. If the perlite is soft and friable, brecciated, or extensively jointed, ripping is employed with significant cost savings. Blasting is required where perlite cannot be readily broken using rippers, but care must be taken to achieve fragmentation without production of excessive fines or oversized material. Once broken and sometimes crushed, the perlite is loaded on trucks or conveyor belts by front-end loaders, excavators, or scrapers for transport to the processing plant. Selective mining is used to minimize rhyolite or obsidian. If perlite textures vary, it is often blended to produce consistent milling characteristics and to meet market specifications.

PROCESSING

Perlite processing follows three main lines: crude, expanded, and microspheres. Crude perlite and expanded perlite are the main products. The expanded perlite is divided into foam (multicellular) and microspheres (mostly unicellular).

Table 4. Size distribution for some Basin Perlite products

Product*	Sieve Size Range	Major End Uses
PQP-100	-6 +12	Horticulture
PQP-120	-12 +30	Horticulture, ceiling tile
PQP-130	-12 +50	Ladle topping, loose-fill cavity insulation, masonry
PQP-145	-16 +50	Loose-fill insulation, masonry
PQP-150	-30 +100	Fire-resistant insulation
PQP-160	-50 +100	Ceiling tile, fire-resistant insulation
PQP-170	-50 +200	Pipe insulation
PQP-180	-100 +200	Cryogenic insulation
PQP-192	-200	Soap
PQP-200	-200	Ceramics
PQP-500	-100	Joint compound

Adapted from Basin Perlite literature.

* Most of these products are blended from various bins per customer specification.

Crude Perlite

The size of the expanded perlite particle is determined mainly by the particle size of the feed to the furnace. The final particle-size distribution will vary among producers, but basic milling and classifying processes include primary and secondary crushing, drying, classification, tertiary crushing, and dust collection. Crude perlite, usually stockpiled, is reduced in size through jaw crushing prior to drying. Following drying, particle size is further reduced through additional crushing and sized over vibrating screens. Variants on this general procedure include the use of gyratory cone crushers for primary crushing, and impact mills, rod mills, hammer mills, gyrodisks, and roll crushers in secondary and tertiary crushing. The basic perlite size grades are stored in silos and can be blended to meet the specifications of customers (Table 4).

Processing has changed in recent years to favor some particle sizes over others. This market-driven size preference is illustrated by the shortage of horticultural grade material (hort) and the ramp-up in microspheres production in the early 2000s. Plants were, as much as possible, reorganized to favor coarser grades (jaw crusher feeding a cone crusher, for example) and to enhance fines production. Some middle grades may become unsalable under certain market conditions and are wasted when this strategy is used.

Expanded Perlite

Foam (Multicellular)

When heated to softening, perlite can expand to as much as 40 times its original volume. Expansion is generally achieved at temperatures that range from 600° to 900°C in one of two basic furnace types: the stationary vertical expander or the rotary horizontal expander. Both operate on the same principle. Crushed and sized perlite is rapidly introduced into a hot zone, where volatilization of the combined water within the glass is coincident with the softening of the glass. The resulting frothy particle (Figure 3) exhibits extremely low-density, high surface area and light or white color.

The stationary vertical furnace is the more widely used of the two furnace types (Jackson 1986). Sized perlite, which may or may not be preheated, is gravity-fed through a side port into the hot zone where expansion occurs. The expanded particles are carried by updraft into the cyclone collection system. Expanded particles pass through the hot zone and drop from the system, while shattered fines are carried upward and are collected in the baghouse.

Courtesy of New Mexico Bureau of Geology and Mineral Resources.

Figure 3. Expanded horticultural perlite showing thin-walled multicellular grain

Within a rotary horizontal furnace, the feed falls into the hot zone toward the top of the flame. As in the vertical furnace, the feed may or may not be preheated before introduction into the hot zone. As the furnace rotates, the feed travels by lifters and spirals down the length of the tube, and the expanded product is drawn by draft into the cyclone and baghouse system. Following the cyclone sizing, the product may be milled and classified for use as filter aid or may be surface treated for other applications. Final products are bagged, then loaded as bulk into railcars or trucks (of ten pressure differential) or into containers.

The densities and particle strengths of the expanded perlite required by the end user vary by application. The final density and recovery of the product as well as the fuel efficiency of the expander can be improved through preheating the furnace feed (Jackson 1986). For vertical furnaces, preheating is achieved in an external, separate heater. In horizontal furnaces, the feed is preheated as it is transported between the inner and outer shells of the furnace to the hot zone where expansion occurs. Preheating the coarser grades can be important because of the relationship between the ratio of volume to surface area of the particle, heat transfer, and residence time in the hot zone of the furnace (Jackson 1986). Although some flexibility of finished product properties can be achieved through adjustment of furnace conditions and through preheating, it is important to note that all perlites do not expand alike. Kadey (1983) has written that perlite containing excessive combined water is likely to shatter upon expansion, whereas perlite containing less water is likely to produce higher-density products. Perlite is also classified as live or dead based on its expansion characteristics (Murdock and Stein 1950). A typical value of 3.2% to 3.7% combined water in perlite seems to work best in most situations.

Microspheres (Unicellular)

Feedstock for microspheres production is crude perlite. At one microspheres operation, the former Basin Perlite in Utah, the general processing method was as follows:

1. Crude perlite was pneumatically conveyed from bins to the microspheres plant.
2. The perlite was ground in a roller mill to $-75\ \mu\text{m}$ (-200 mesh) and passed through a double whizzer that returns oversize ($+75\ \mu\text{m}$) to the roller mill for regrinding.

Courtesy of New Mexico Bureau of Geology and Mineral Resources.

Figure 4. Uncoated perlite microspheres expanded from very-fine crude perlite. The glassy, spherical, hollow particles consist of one or more microcellular bubbles with intact walls. Note the holes or "blow-outs" on the prominent particle near the center of the scanning electron microscope (SEM) photo and on a few other particles.

Table 5. Physical properties of selected Silbrico microspheres products

Grades	Sil-32	Sil-42	Sil-35	Sil-43
Oil absorption ASTM-D-1483, grams oil per 100 cc	30	36	38	40
Hygroscopic moisture m	0	0	0	0
Surface Hardness	7.0	7.0	7.0	7.0
Thermal conductivity, $\text{Wm}^{-1}\text{K}^{-1}$	0.36	0.40	0.41	0.43
Color	White	White	White	White
Dry bulk density, kg/m^3	112	136	145	168
Average particle size, μm	75	45	40	35
Effective particle density (in resin), kg/m^3	179	250	250	303
Particle size range, μm	1–300	1–210	1–150	1–150
Fusion point, $^{\circ}\text{C}$	1,260	1,260	1,260	1,260

Adapted from Silbrico Corporation literature.

3. The $-75\ \mu\text{m}$ material was jet-stream classified to $-75 + 10\ \mu\text{m}$ ($-200 + 1250$ mesh) with an average particle size of 25 to $30\ \mu\text{m}$.
4. This material was fed to a 4.5 ktpy (3-shift) vertical furnace for expansion.

The expansion furnace burned natural gas, and operated at a temperature range of 480° to 600°C . Upon expansion, glassy, spherical-shaped hollow particles were produced, which consisted of one or more microcellular bubbles (Figure 4). This product (BASIN 500) had a particle size of 100% -100 mesh ($160\ \mu\text{m}$), an average particle size of 250 mesh ($60\ \mu\text{m}$), and a bulk density of 112 to $144\ \text{kg/m}^3$.

Depending on customer requirements, the microspheres could be surface modified with either silicone or silane. These coatings increase the hydrophobicity (water repellency) of the microspheres. The finished product was then conveyed to storage bins for shipment to customers.

See Table 5 for additional information on physical properties of microspheres.

Table 6. End uses of crude and expanded perlite in North America*

Type	Category	Application	Remarks and Properties
Expanded	Formed	Insulating board	~70% perlite + cellulose + binder
		Ceiling tile	~75% perlite + cellulose + binder
		Pipe insulation	Perlite + sodium silicate + fiber
	Construction	Wallboard	Decreases shrinkage, reduces weight
		Loose fill	Wall cavities (silane or silicone)
		Masonry fill	Masonry block fill (silicone or asphalt)
		Plaster aggregate	Reduced rebound when gunned
		Concrete aggregate	Yields 15–50 lb/ft ³
		Joint compound	Enhanced workability (microspheres)
		Door core	Fireproofing; door liner ~75% perlite
		Coatings	Sprayed; texturizer
		Cryogenic	Fills annular space between tank walls
		Carrier	Cosmetics
		Filter aid	Food, beverages, liquids; Blunt 1994
		Horticultural	Retains water, aeration; Blom 1994
		Hay	With 50% bentonite, binding hay cubes
		Filler	Plastics, sealants, caulks, adhesives
		Animal litter	Poultry litter, animal feed
		Textile	Gentler stonewashing of fabric
Crude	Stone	Decorative	Landscaping; golf sand traps
	Abrasive	Sandblasting	Silica substitute; polishes and cleansers
	Foundry	Ladle topping	Insulating crust and coagulant of silica
	Silica	Acid treatment	CaF ₂ scavenger in phosphates
	Pottery	Flux	Feldspar substitute
Research	Surface charge	Activated perlite	Expanded and crude; Dogan, Alkan, and Cakir 1997.
	Microspheres	Fluidized bed	Sodeyama et al. 1996, 1997a, 1997b.
	Synthetic	Zeolite	Christidis, Galani, and Marcopolous 2000.
	Substitute	Feldspar	Mogilski 1990; Bozadgiev 1995.

END USES

In the United States in 2004, perlite end uses were construction products, 62%; horticultural aggregate, 13%; fillers, 10%; filter aids, 9%; and other uses, 6% (Bolen 2005). Worldwide, construction is by far the dominant end use (Englert 2000).

The commercial physical properties of expanded perlite include low bulk density, physical resilience, chemical inertness, low thermal and acoustical conductivity, fire resistance and nonflammability, and water retention. Crude perlite ranges from light gray to black in outcrop. In contrast, the most distinguishing characteristic of expanded perlite, other than low density, is brilliant white color. Even in end uses where color is not paramount, white is the preferred

color, even at a cost penalty. The brilliant white of expanded perlite offers aesthetic advantage in light colored, visible surface coatings.

The greater hardness of perlite, its chemical resistance, and porosity are important in horticulture when soils are wet for prolonged periods or where drainage, aeration, and water retention are required. Addition of perlite to dry soils aids retention of water. The high brightness of finely ground perlite applied to the surfaces of seed blocks reflects light to the underside of seedlings and promotes rapid and sturdy growth. Typical specifications (Chang 2002; Harben 2002) for crude perlite by mesh size and end use are shown in Table 4. Many end uses are summarized in Table 6 and are described in works by Kendall (2000), in which Table 2 lists valuable perlite characteristics related to application; and by Barker et al. (2002); and Harben (2002).

Microspheres

Perlite microspheres are inert, nontoxic, low density, white, micron-sized functional fillers (Table 7).

Used mainly in joint compound as part of wallboard installation, perlite microspheres provide the following properties to joint compound:

- Reduce weight and shrinkage
- Lessen cracking and sagging

- Reduce drying time
 - Enhance workability
 - Improve impact resistance, nailing, stapling, and sanding
- Non-joint compound end-use applications include the following:

- Textured and acoustical coating mixes
- Cultured marble
- Adhesives and sealants
- Wall-patching compounds
- Stucco
- Auto body putty
- Thermo-set castings
- Syntactic foam
- Sheet molding (SMC) and bulk molding compounds (BMC)
- Rotational molding
- Fiber-reinforced product (FRP) spray and hand lay-up
- Tub and shower enclosures
- Specialty coatings
- Block filler paints

TESTING

Perlite deposits are evaluated for suitability in four main end uses: horticulture, construction, filter aids, and fillers/extenders. Basic testing of expanded perlite, done for exploration, usually is loose weight (expanded density, furnace yield [mass balance]), sieve analysis of expanded perlite, brightness, and sinters. Additional end-use specific tests (Giles and Poling 1991) may be performed later. For example, a special grinding regime and chemical tests are added to filter-aid-grade perlite testing, owing to its use in the food industry. Tests for filter aids are given in the *Perlite Institute Handbook* (Anon. 1984), the U.S. Food Chemical Codex, and Breese and Barker (1994).

Facilities for testing perlite, both crude and expanded, are sparse on a commercial, cost-effective, or readily accessible basis. Little information or data are accessible regarding perlite testing of many products (Barker, Hingtgen, and Bowie 1987; Barker and Harris 1990). To maintain quality and performance standards, the Perlite Institute, formed in 1949, assembled a comprehensive testing procedure and specification manual, which includes tests developed by the Perlite Institute, as well as specifications established by the American Society for Testing and Materials (ASTM). The *Manual of Test Methods* (Perlite Institute 1984) is available through members of the Perlite Institute in Harrisburg, Pennsylvania, via its Web site. Barker et al. (1987) and Breese and Barker (1994) give descriptions of testing equipment, procedures, and calculations; some are adapted slightly from the Perlite Institute tests.

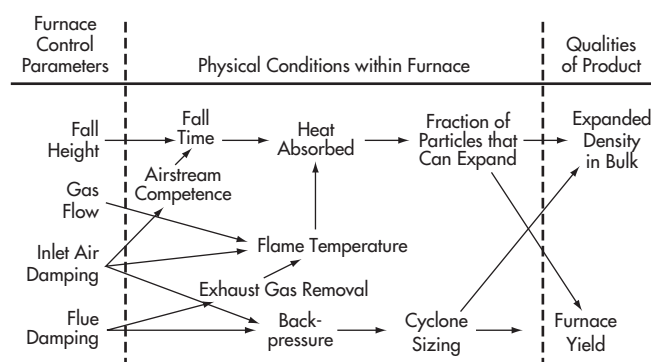

Perlite testing is not an exact science. Interpretation of results requires experience, and scaling up from laboratory results demands caution. Scale-up problems abound in designing full-scale plants based on bench-scale expansion tests. No correlation has been demonstrated between bench-scale expansion tests using horizontal furnaces and similar tests in commercial plants (Kadey 1983). Scaling up from vertical furnace bench testing to full-scale testing has better correlation, but full-scale testing must be done prior to investment in mining or processing of perlite.

Use of perlite microspheres is relatively new, and testing procedures and specifications are often kept confidential. For use in joint compound, bulk density and particle-size distribution are the main criteria (Table 5). An important test for all end uses is crystalline silica content so that compliance related to health regulations can be determined.

Adapted from Barker and Harris 1990.

Figure 6. Interactions between control settings, furnace conditions, and product quality in a perlite furnace

Expansion

Efficient expansion of perlite particles is highly dependent on their surface-area-to-volume ratios. A narrow, unimodal size distribution is preferred for testing. The small size of laboratory expansion-furnace tubes (typically 1 to 2 m long) makes it sensitive to feed particle size (Figure 5). Expansion in a 1-m tube is best using the -50 +100 mesh fraction at 700°C, although the -30 +50 mesh fraction can also be used at higher temperature of up to 800°C.

Perlite expansion is a function of its composition (especially water content), fluxing agents (calcium, sodium, and potassium), feed rate to the furnace, fines in the feed, softening temperature, furnace temperature, and particle residence time in the flame. Additional factors affecting perlite expansion are humidity, barometric pressure, and ambient air temperature (Figure 6). Seasonal variation and reaction to changing elevation if the furnace is moved are measurable. Ambient conditions at the furnace location (temperature, humidity, combustion, air flow, etc.) are additional variables. Perlite expansion is thus more art than science and is highly operator dependent.

More heat must penetrate some perlite particles to achieve good expansion. These tend to produce particles with round, multiple cells and thick bubble walls that retain their integrity, useful in construction and horticulture. Preheating the perlite feed, increasing the furnace temperature, and/or optimizing feed size are possible ways to mitigate this or decrease energy use. Other perlites are more responsive to furnace heat and tend to shatter when expanded, producing bubble-wall shards forming better filter aids (Blunt 1994). Either outcome provides a commercial product.

Expansion and testing of perlite is done under varying conditions, so a standard must be used. The higher the expanded density of an unknown perlite sample compared to the standard, the more energy-intensive perlite production will be. Test results can also be reduced to the ratio between an unknown sample and the standard to dampen some of the variability or can be normalized on the standard. Finally, as many variables as possible should be controlled, especially by using the same technician to do the tests.

Commercialization

Laboratory-expanded perlite is handled differently than commercially expanded perlite. Laboratory perlite is carefully moved between containers in small amounts compared to large tonnages of expanded perlite air-classified in plants. The laboratory material has less size reduction from handling and has lower expanded density and fewer fines for otherwise identical expanded perlite. Commercial feed, and hence product, often is not sized as accurately as the material tested in laboratories. These relationships must be considered when scaling up to commercial production. The density to which a perlite expands affects many of its commercial properties, so the expanded density is crucial to assigning a given perlite to its most favorable end uses.

Test results generally cannot be interpreted separately. Scaling up from laboratory results must be done with caution. Pilot-plant testing must be done prior to construction of commercial processing facilities.

PERLITE PRICES

The perlite market is sensitive to trends in the construction and horticulture sectors. Expanded perlite comprises the majority of worldwide consumption. Historical perlite production and average prices in the United States are given in DiFrancesco and Bolen (2004), and recent data are in Table 2. All prices are free on board (f.o.b.) plant with transportation additional.

Crude Perlite

Crude perlite is used as an expanded furnace feed, slag coagulant, abrasive, metal cleanser, and silica source. Typical prices for crude perlite range from US\$27.50/t to US\$449.50/t. In the early 2000s, horticultural perlite reached US\$95/t.

Expanded Perlite

Most of the market for expanded perlite is in construction-related products such as roof insulation board, acoustical ceiling tile, pipe insulation, concrete, and plaster aggregate. Prices for expanded perlite range from US\$190 to US\$660/t.

Microspheres

Prices for microspheres depend on packaging and on whether they are coated with silicone or silane. Pricing ranges from US\$0.44 to US\$0.66/kg, or US\$440 to US\$660/t.

TRANSPORTATION AND PACKAGING

Expanded perlite bulks out before it tons out against the carrier weight limit, so most perlite is shipped unexpanded. Imports usu-

ally arrive by ship at ports with convenient road or rail access to expanding plants. In the United States and Canada, shipping to customers is generally by rail, and, as in Europe, the perlite is expanded locally for use nearby. Ocean freight exports from Greece to the United States began in 1983 and continue.

Fine grades of perlite are often moved in bulk in pressure differential (PD) railcars or truck trailers. Perlite is distributed in several packaging sizes and types. Bags and various supersack systems are common. Overseas, perlite is shipped packaged in containers.

Filter aids are shipped expanded in bags as light as 7.5 kg. They are usually handled pneumatically in bulk and require less line pressure and pump horsepower than competing products. Perlite is easily fluidized for unloading (Blunt 1994).

Microspheres

Customers purchase microspheres in 0.12-m³ plastic-lined bags (16 to 22 kg) or in 227-kg supersacks. Microspheres are shipped in bulk by PD truck (bulks out at approximately 6 t) or PD railcar (bulks out at approximately 23 t). Some producers, like the former Basin Perlite, also ship packaged microspheres offshore utilizing containers.

ECONOMIC AND COMPETITIVE FACTORS

No tariff is applied on perlite imported into the United States, where the depletion allowance is 10%.

Substitutes

Expanded perlite competes with polystyrene, vermiculite, and pumice as an ultra-lightweight aggregate, thermal and acoustical insulator, and bulking agent. The resilience of perlite is preferred for concrete under wet conditions. In cryogenic applications, where the insulating material must have low thermal conductivity, perlite dominates the market. The worldwide availability of perlite deposits and expansion facilities and lower price make it more competitive than vermiculite where physical resilience or brightness is paramount.

In horticulture, perlite, polystyrene beads, and vermiculite can be used selectively in different market segments. In loose-fill insulation, polystyrene beads and vermiculite are competitive.

Pumice must be shipped in its natural, lightweight form and hence is less competitive (Evans 1993) because of the very high transport costs, although higher grain-strength benefits aggregate use.

Filter aids have long been dominated by diatomite. The irregular and platy particles of milled perlite perform well in rotary vacuum filters and in filter-aid applications needing high flow rates without high clarity.

Environment and Regulation

Perlite is composed of amorphous volcanic glass with trace crystalline materials such as quartz and feldspar. Quartz is present in low amounts in perlite, generally ranging from <1% to 5%. The crystalline silica in perlite occurs primarily as alpha and beta quartz and sometimes as cristobalite or tridymite, which are more reactive in the body than alpha and beta quartz (Sax and Lewis 1988). When perlite is mined, processed, or utilized, some of the crystalline silica may become airborne, but little of this occurs as respirable dust (<5 to 10 µm in diameter). The relationship of pulmonary fibrosis in workers exposed to crystalline silica dust for widely varying lengths of time is well documented (Sax and Lewis 1988), and the perlite industry has addressed these health issues for many years. Perlite dust is treated and regulated as a nuisance dust with appropriate exposure limits enforced.

In 1987 and 1988, the International Agency for Research on Cancer (IARC), under charter by the World Health Organization, reviewed literature regarding the health effects of crystalline silica

(IARC 1987, 1988). IARC then classified crystalline silica as a Class 2A (probable carcinogen) in humans. This finding was based on limited evidence in humans and sufficient evidence in animals (Miles 1998; SME 1998) and only applies to inhaled (respirable) crystalline silica, not to dust that is ingested or contacted. The carcinogenic risk of crystalline silica was revisited in 1996 with a recommendation and reclassification of quartz and cristobalite as Group 1 (carcinogenic in humans) published in 1997 (IARC 1997). Silica regulation has ensued as many nations, including U.S. federal and state agencies, consider the findings of IARC when writing health-related legislation.

The regulation of silica in perlite and other materials is complex and ever changing. Miles (1998), SME (1998), and Health Council of the Netherlands (SZW 2003) provide an overview. The U.S. regulations presuppose that untreated mixtures of products and crystalline silica present the same hazard as any component of the mixture comprising more than 1% by weight or volume. If a component is a suspected carcinogen, then the threshold becomes 0.1% by weight or volume, and a carcinogenic warning label is required if this value is exceeded. Dilution of the mixture to below the threshold level of 0.1% can eliminate the need for labeling. Thus, the two key values for crystalline silica in perlite are 0.1 and 1.0 wt %.

The industry has responded to silica regulations by mobilizing several organizations, mandating protective equipment wear by workers, updating material safety data sheets (MSDSs), dust reduction and monitoring, development of test methods suitable to the 0.1 and 1.0 wt % thresholds, and training. Even though crystalline silica is of concern, perlite dust is not harmful itself (Cooper and Sargent 1986) and is now treated as nuisance dust. Fugitive dust generated on windy days is often noticeable in communities surrounding perlite processing.

The crystalline silica content of perlite filter aids must be determined prior to the pilot-plant stage of development. The crystalline silica content of both crude and expanded perlite is regulated as a carcinogen. Testing for crystalline silica is done routinely using x-ray diffraction (XRD) methods (Barker and McKee 1990; Hamilton and Peletis 1990; McKee, Renault, and Barker 1990; Miles and Hamilton 1991; Miles and Harben 1991; Renault, McKee, and Barker 1991, 1992; SME 1998; Miles 1998). Key levels are 0.1 wt % and 1 wt % crystalline silica. The total crystalline silica along with the amount of quartz, cristobalite, and tridymite should be determined. The crystalline silica from perlite is usually diluted during end use and rarely presents a problem unless very high concentrations are found. Perlite is very well suited to XRD detection of trace crystalline silica because it is mostly amorphous volcanic glass. Other methods of analysis for crystalline silica include x-ray fluorescence (XRF), optical petrography, electron microscopy, wet chemistry, heavy liquid separation, solubility, and infrared absorption.

FUTURE TRENDS AND OUTLOOK

The perlite industry continues to mature. Growth is slow but steady, and consolidation into fewer and larger firms has begun in North America. S&B has penetrated markets aggressively worldwide and is clearly the industry leader in the mid-2000s. The perlite industry in the United States continues to undergo rapid change and increased competition.

Microspheres

The demand for perlite microspheres in North America is expected to increase as the wallboard market grows. As construction practices change outside of North America, such as from lathe and plaster to wallboard, the international market for perlite should grow significantly.

In addition, some joint compound producers project a higher growth rate for "lightweight" joint compound compared to "standard or all purpose" in the western United States. This is being driven by (1) an increased use of lightweight joint compound and (2) commercial and residential construction growth in this region of the United States. Lightweight joint compounds have a higher microspheres content (>30 wt %) than all-purpose joint compounds (<15 wt %). Producers have performed R&D for producing a super-lightweight joint compound that will require a "lower bulk density" perlite microspheres product.

Non-joint-compound end uses for perlite microspheres should continue to grow, as the producers begin to direct more market development in this area. Also, R&D efforts by producers and consumers will probably result in new end-use applications.

The North American joint compound market for perlite microspheres is estimated by wallboard producers to be approximately 55 ktpy. Annual growth rate for the next few years is projected at about 2.5% to 3.0%. The major consumers of perlite microspheres for joint compound production are U.S. Gypsum (>50%), National Gypsum, Hamilton Materials, BPB Gypsum, Lafarge Gypsum, and Georgia-Pacific Gypsum. U.S. Gypsum has 20 joint compound plants in North America: 13 in the United States, 5 in Canada, and 2 in Mexico. In addition, it has a plant in Malaysia. Smaller producers in the United States include Magnum Products, Murco Wall Products, Freeman Products, Southern Wall, Solids Products, Supro, Tool World, Custom Building Products, Kadex, Welco Manufacturing, and Century Industries.

Non-joint-compound consumption is not known, because it is a fragmented market (i.e., a wide variety of end uses). However, industry estimates place it at about 15 ktpy.

Silica

Crystalline silica in general is tending toward an asbestos- or arsenic-style debate (Chajet 2004). In the face of large declines in silica mortality, various government and private groups are proposing very stringent silica exposure rules. Silica deaths declined to less than 180 deaths in 2000 (compared to about 1,800 in 1969), owing to reductions in exposure set in place years ago. This trend suggests that silica mortality may be on the verge of elimination in the next few years as deaths approach zero. An opposing trend is the massive increase in silica-related lawsuits, including at least 35,000 in 2003 alone (Chajet 2004). U.S. Silica has a total of more than 32,000 silica claims (Ulizio 2004), mostly in Mississippi (57%) and Texas (33%), which are states favorable to these types of lawsuits. As summarized by Chajet (2004), the situation is as follows:

- Restriction of the "sophisticated buyer" defense is developing for producers delivering in bulk to commercial customers.
- Product information may need to be supplied to customer employees at supplier expense.
- A silica health insurance exclusion is being applied to renewals and new policies.
- Temporary or contract workers must be protected from harm.
- Companies are reviewing hazard information to ensure that all high-risk workers (both those employed by the company and those who work for its customers) are informed.

Drastically lower silica thresholds have been proposed and are likely to be implemented, perhaps at great cost to the perlite industry.

ACKNOWLEDGMENTS

The authors wish to acknowledge the contributions of Nikhil Trivedi, Steve Castor, Peter Harben, Brian Coope, Judith Chegwidden, Tim Hall, Ric Breesse, Richard Chamberlin, Nelia Dunbar, Pat

Freeman, Fred Bodycomb, Charles Smith, Keith Papke, Armando Alatorre, and Steve Herron. The authors discussed various aspects of this chapter with these perlite producers: S&B, Basin, Cornerstone, Silbrico, World, and Grefco; they are thanked for their contributions.

Phosphate Rock

Patrick Zhang, Ronald Wiegel, and Hassan El-Shall

INTRODUCTION

Phosphorus is essential to plant and animal life. It provides the material for skeletal bone structure in animals and for cell membranes in both plants and animals. The largest and least expensive source of phosphorus is obtained by mining and concentrating phosphate rock from the numerous phosphate deposits of the world. The principal use for this phosphate rock is the manufacture of fertilizer ingredients for food-crop nutrition and the production of animal feed supplements for use in promoting healthy and quick skeletal growth for meat-producing livestock.

Phosphorus is also the second most abundant mineral in the human body, after calcium. This mineral is essential for the healthy formation of bones and teeth and for processing many of the foods that are consumed. It is also a part of the body's energy storage system and helps maintain healthy blood sugar levels. Phosphorus is also found in substantial amounts in the nervous system. Regular contractions of the heart are dependent on phosphorus, as are normal cell growth and repair.

Phosphate deposits are widely distributed throughout the world, with major economic ore bodies located in the United States, Morocco, China, Russia, South Africa, Jordan, and Australia. These deposits are generally surface mined, with a minor portion mined underground. The United States is currently the world's largest producer of phosphate rock, accounting for 25% to 30% of world production; Florida and North Carolina account for about 85% of this. The gradual decline in U.S. production and increases elsewhere could soon lead to the United States, Morocco, and China producing about equal amounts of phosphate rock.

Untreated phosphate rock, which is a substituted calcium phosphate containing minor amounts of carboxy, hydroxy, and fluoride ions, is only slightly soluble in groundwater and therefore provides little available phosphorus for plant nourishment. More than 90% of the phosphate rock consumed in the United States is used to manufacture wet-process phosphoric acid by reaction with sulfuric acid. This phosphoric acid is then used to produce various fertilizer ingredients, animal feed supplements, and some other phosphorus chemicals. The phosphatic fertilizer ingredients include diammonium phosphate (DAP), monoammonium phosphate (MAP), and triple superphosphate (TSP). DAP and MAP are produced by reacting the phosphoric acid with ammonia, and TSP is obtained by reacting the phosphoric acid with phosphate rock. Recent information indicates that 50% of U.S. phosphoric acid production is exported as either commercial acid or a reacted fertilizer

ingredient, and this accounts for more than 50% of global interregional trade in phosphates, 90% in MAP and 75% in DAP.

The world phosphate market began to recover in 2002, following more than 2 years of weak market conditions caused by lower fertilizer demand, excess capacity, and changes in global supply patterns. Adverse economic conditions significantly affected producers in the southeastern United States that rely heavily on export sales. Since late 1999, three phosphate producers filed for bankruptcy, two phosphate plants in Florida closed permanently, and several other plants and mines temporarily closed or reduced their output. Domestic production of phosphate rock and phosphoric acid, and fertilizer export shipments, increased in 2002. Although the United States has remained the largest global supplier of phosphate fertilizers, its share of the world DAP export market fell from about 65% in 1998 to less than 50% in 2002 (Prud'homme 2002). The current recovery, however, has been accompanied by increased prices for raw materials such as ammonia and sulfur, and so profit margins remain slim.

World production of phosphate rock was estimated to reach 138 Mt in 2003 (Jasinski 2004). Low-grade sedimentary phosphate ores containing calcareous impurities such as calcite or dolomite in addition to siliceous gangue must be beneficiated to meet the expected continuing demand. For more than 65 years, flotation has been successfully applied to both sedimentary and igneous phosphates with siliceous gangue (Houot 1982). Meanwhile, calcination was the only technique used for upgrading sedimentary phosphates with carbonate gangue anywhere other than China and Utah, in the United States (Abdel-Khalek 1982). Calcination has several recognized drawbacks; these include the high energy consumption (Elgillani and Abouzeid 1993) and the lower acidulation reactivity of the calcined products (Abdel-Khalek et al. 1994). As a consequence, some plants no longer use the calcination process, such as the El-Hamrawien phosphate plant on the coast of the Red Sea in Egypt. It is therefore important to develop an alternative technique to upgrade the sedimentary phosphates with carbonate gangue minerals.

In Florida, phosphate mining and processing changed only incrementally during the past half century. Current practice begins with huge draglines removing the overburden and dumping it in spoil piles adjacent to the mine pit. The phosphate ore (matrix) is scooped out, placed in earthen wells, slurried with high-pressure water, and pumped to the beneficiation plant. At the plant, the matrix is washed to complete disaggregation, screened to produce a

* Estimated

† That part of the reserve base that could be economically extracted or produced at the time of determination. The term *reserves* need not signify that extraction facilities are in place and operative. Reserves include only recoverable materials; thus, terms such as *extractable reserves* and *recoverable reserves* are redundant and are not a part of this classification system.

‡ That part of an identified resource that meets specified minimum physical and chemical criteria related to current mining and production practices, including those for grade, quality, thickness, and depth. The reserve base is the in-place demonstrated (measured plus indicated) resource from which reserves are estimated. It may encompass those parts of the resources that have a reasonable potential for becoming economically available within planning horizons beyond those that assume proven technology and current economics. The reserve base includes those resources that are currently economic (reserves), those that are marginally economic (marginal reserves), and some of those that are currently subeconomic (subeconomic resources).

pebble product (1 × 19 mm), and then hydrocycloned to remove fine phosphatic clay (passing 150 mesh), which is collected in clay settling ponds. The remaining flotation feed (16 × 150 mesh) is upgraded using the Crago double float process, which consists of high solids conditioning with fatty acid/fuel oil at about pH 9.0 to 9.5; flotation of the phosphate mineral; acid scrubbing of the concentrate to remove the reagents; and, finally, flotation of the residual fine sand from the phosphate mineral using an amine. Virtually all the phosphate rock produced is acidulated with sulfuric acid in nearby chemical plants, and the resultant phosphogypsum precipitate is filtered from the phosphoric acid and stored in large gypsum ponds and stacks.

Several problems are becoming more serious in Florida, and these will require changes in the not-too-distant future if the state is to maintain its leadership role in phosphate rock and fertilizer production:

- As mining progresses to the southern and western parts of the state, the phosphate matrix contains less pebble product, is becoming lower grade, and is more contaminated with dolomite.
- Because of increased environmental concerns, mining and production permits are much more difficult to obtain and have tighter restrictions on land use, water consumption, waste disposal, and reclamation of clay ponds.
- Because of recent bankruptcies, government entities are more concerned about environmental liability, especially as related to clay ponds and phosphogypsum stacks and ponds.

The technical problems have been recognized for a number of years, and measures have been taken to address them, although economic solutions are not all at hand. The political pressures are more surprising and will perhaps dictate the acceptance by industry of compromises that will lead to higher capital and operating costs for future and continuing operations. One of the leaders in calling attention to and attempting to solve these pressing problems is the Florida Institute of Phosphate Research (FIPR), which is supported by a portion of the severance tax paid to the state by the mining companies. Most of the funds expended by FIPR support contract research, which is awarded based on proposals submitted by companies, universities, and consultants, although there are a small number of internal research projects as well. Among the projects funded through FIPR are those addressing phosphate rock mining and mineral processing, fertilizer chemical processing, environmental concerns, and mined land and gypsum stack reclamation.

PRODUCTION AND TRADE, RESOURCES AND RESERVES Phosphate Rock

The current, most concise, and authoritative statistics on phosphate rock production and identified reserves worldwide can be found in the U.S. Geological Survey (USGS) *Mineral Commodity Summaries 2004*; these are summarized in Table 1.

Table 2 lists phosphate rock production by country from 1994 through 2003.

The industrial revolution of the nineteenth century provided a ready supply of sulfuric acid. This, coupled with the development

† na = not available.

of the rich phosphate deposits of Florida, North Carolina, Tennessee, and North Africa, was the main basis for the phosphate industry in Europe, North America, and Oceania. Today, the United States, China, and Morocco produce about two thirds of the world's phosphate rock. Morocco alone accounts for one third of the international trade in phosphate rock. China has emerged in the past decade as the third largest producing nation, whereas the countries of the former U.S.S.R. saw their share decline to 8% from nearly 25% of the world phosphate fertilizer production because of the collapse of their domestic markets.

Globalization is reflected in the increase in international trade. Although phosphate rock trading has declined from almost 40% in 1980 to about 25% today from its country of origin, if processed phosphates are included, about 60% of the phosphate is exported. Morocco and the United States account for nearly half of these exports, with the United States exporting more than 50% and Morocco more than 95% of their respective phosphate production. The top three rock exporters include Morocco, Jordan, and the former U.S.S.R., accounting for about 50% to 60% of the world rock exports. Togo and Syria also export all or most of their production.

Processed Phosphate

Figure 1 shows world production, imports/exports, and consumption of phosphate fertilizers (in tons of phosphate [P_2O_5]) for five crop years.

Thirty years ago, the main form of traded P_2O_5 was phosphate rock, which was processed in superphosphate and compound fertilizer plants, predominantly in the developed world. Over the last 30 years, the role of phosphate rock as an export carrier of P_2O_5 has declined sharply as vertically integrated industries have been developed at or close to the site of rock mines. World phosphate rock exports fell from 53 Mt of product in 1979 to 27 Mt in 1993 but subsequently increased to stabilize at about 30 Mt. The U.S. industry, for example, was exporting about 10 Mt of rock on average from 1966 to 1986; this was reduced to a few thousands tons in

recent years. Correspondingly, world trade in processed phosphate products increased substantially (Table 3). Almost all the phosphoric acid plants in Western Europe have closed, for economic and environmental reasons.

As is indicated in Table 3, ammonium phosphate as MAP and DAP accounts for most of the increase in processed phosphate trade. Table 4 shows production data from major producers (countries) of phosphate fertilizer.

Total world exports of phosphate fertilizers increased from an average of a few million tons during the 1970s to the current level of about 13 Mt. Indeed, there has been a general tendency for processed phosphates to substitute for phosphate rock in the international trade. The United States is the leading exporter of phosphates, with about a 40% share of world trade (see Table 5).

From the mid-1970s to the early 1980s, most of the increase in processed phosphate trade was in the form of phosphoric acid, but subsequently it was DAP, which accounted for most of the increase.

Asia is the most important importing region for ammonium phosphates, followed by Western Europe and Latin America (see Table 6). Chinese DAP imports account for roughly one quarter of

the world trade. Although its DAP imports are relatively small considering its population, India is the world's leading importer of phosphoric acid for use in DAP production.

GEOLOGY

Mineralogy

Generally, phosphate minerals are found in igneous, metamorphic, and sedimentary deposits. In sedimentary marine ores, the phosphate is usually a carbonate fluorapatite. In igneous deposits, the phosphates have compositions close to that of fluorapatite. In some deposits, Ca-Fe-Al and Fe-Al phosphates are associated with apatite (McClellan and Germillion 1980). Currently, the apatites recovered from igneous and metamorphic rocks have commercial importance, but such apatites supply only a small fraction of the world market. On the other hand, sedimentary phosphates have been, and no doubt will continue to be, the major source of commercial raw material for the phosphate industry.

These sedimentary apatites, because of their widely differing modes of chemical composition, display large variations in physical forms and types of associated gangue. Accordingly, these ores fall into one of the following three principal categories (Lehr and McClellan 1973):

1. Siliceous ores. In this type, the major gangue mineral is quartz, chalcedony, or opaline forms of silica. The Bone Valley deposit in central Florida, the upper unit of the Hawthorn Formation in north Florida, and the upper zone of the Hawthorn Formation in central Florida belong to this type. Phosphate ores in Australia and Senegal also fall under this category.
2. Carbonaceous ores. This type of ore consists of phosphatic limestones or calcareous phosphates in which calcite, dolomite, or ankerite is mixed with the phosphate, or which occurs as intercalated seams. These include the lower zone of the Hawthorn Formation in central Florida; most of the phosphate deposits in Hubei and Guizhou provinces, China; the Kara Tau Formation in Russia; a majority of the Mongolian deposits; and some of the Moroccan phosphates.
3. Clayed phosphates. These phosphate ores are associated with gangue minerals containing mainly clays and hydrous iron and aluminum oxides. These gangue minerals are concentrated mostly in the silt and clay size ranges. Most of the phosphate ores in Morocco and Western Sahara, Tunisia, and Togo contain up to 40% clay, whereas the Florida phosphate matrix is composed of one third each of clay, phosphate, and sand.

Geology—Sedimentary

Bateman (1951) gave an enlightening description of the phosphate cycle, summarized here. The sedimentary cycle of phosphorus is quite interesting. Dissolved phosphate enters the soil and is abstracted by plants. It then passes to the bodies of animals and is returned to the soil via their excreta and bones, accumulating into deposits. Phosphate in the deposits may undergo dissolution and end up in the sea, where phosphorus is accumulated or deposited by sea life, embodied in to sediments and returned to the land upon uplift. Some of the phosphorus in the sea is consumed by fish life and passes into birds, whose subsequent excreta have built up great phosphate deposits on some islands of the Pacific. Sedimentary beds of phosphate are formed only under marine conditions in the form of phosphorite. These beds have been formed from early to recent geologic periods and extend with remarkable regularity over thousands of square miles, as in the Bone Valley formation in Florida and the

Qulad Ab doun plateau (Khouribga) in Morocco. Sedimentary deposits of marine origin are sparingly fossiliferous and oolitic.

The high-quality phosphate deposits of the world have been formed by the process of sedimentation, including those of Algeria, Tunisia, and Morocco. These deposits require minimal treatment to produce the most desirable phosphate rock. The Moroccan deposits occur as horizontal beds along with limestone, marls, and clays in which there are 3 to 4 beds up to 2.5 m thick. Deposits in the western United States underlie parts of Utah, Wyoming, Idaho, and Montana, and extend into Canada. The beds are in the Phosphoria formation of Permian age, and the chief bed is about 1.5 m thick. Other major sedimentary phosphate deposits are found in Egypt and Russia. The large phosphate deposits of Florida are generally classified as sedimentary, although they are not strictly sedimentary beds, but pebble deposits derived from a sedimentary phosphate bed. The guano deposits of the Pacific islands are also not sedimentary.

Geology—Igneous

The important igneous phosphate deposits are found in certain intrusive complexes of alkalic rocks. Unlike sedimentary deposits, igneous phosphates generally occur as ringlike structures with limited area extent (generally, 1 to 20 sq mi). Commonly near the center are veins and larger bodies rich in carbonates (calcite, dolomite, siderite, and ankerite) formed either in a molten condition or by metasomatic processes. These carbonate deposits are called carbonatites. Apatite of economic interest can be in the carbonatites or in the alkalic rocks located outward from the central carbonatite. In carbonatites, apatite may be in a weather-enriched surface mantle, or in the unweathered rock (Lefond 1983).

Among the more economically important igneous apatite deposits being exploited commercially are the Khibina nepheline syenite massif near Kir ovsk in the Kola Peninsula in Russia, the Jacupiranga alkalic complex in Brazil, and the Palabora carbonatite in South Africa.

The most important deposit of igneous apatite mined today comes from Kola; the output is more than 9 Mtpy of concentrates with a P_2O_5 grade of 39% from an ore assaying 18% P_2O_5 , 23.1% SiO_2 , and 13.3% Al_2O_3 in a bonded phase of nephelinitic syenites.

Other important igneous phosphate ores are present at Phalaborwa in South Africa. The igneous complex comprises a suite of intrusive alkali rocks that intruded granite gneiss to form three coalescing and concentric lobes. The complex is about 7 km long and varies from 2 km to 4 km wide. The outermost zone consists of syenite and the intrusion is a feldspathic pyroxenite. The next zone consists of an apatite-bearing phlogopitic pyroxenite. Foskor operates an open pit for apatite extraction in a corner of this zone. The apatite varies from 0% to 30% P_2O_5 , averaging 7%, with the principal gangue minerals of diopside and phlogopite. The pyroxenite zone is followed by the foskorite zone, which consists of magnetite, serpentine, and apatite, assaying 6% to 11% P_2O_5 . Originally within the foskorite zone was a carbonatite core hill, which now has largely been excavated and is the large open pit of the Palabora Mining Company (PMC). In 1979 Foskor and PMC reached an agreement in which PMC would extend their open pit, with Foskor sharing the cost, and in return Foskor would receive certain types of ore mined by PMC. Foskor now produces phosphate rock from three sources: pyroxenite ore, foskorite ore, and PMC tailings (Schmidt 1999).

The Brazilian apatites also represent an important source of igneous phosphate ores. They are included in carbonatites (with simple carbonates as in Jacupiranga or as more complex ones with iron carbonates, phlogopite or vermiculite, titanium minerals, barytine, pyrochlore, etc.). The P_2O_5 contents are comparatively low, from 5% for Jacupiranga to 15% for Araxa.

DISTRIBUTION OF MAJOR DEPOSITS

Several excellent references are available on this topic. For mining-oriented discussion of world phosphate deposits, the *World Survey of Phosphate Deposits* (British Sulphur Corporation 1987) is a good resource. For geology oriented information, the best resource may be *Phosphate Deposits of the World* (1986). Only the major phosphate deposits are briefly described in this chapter.

The Americas

Canada

Potentially economic phosphate reserves in Canada are found in Ontario and Quebec. There are also widespread occurrences of phosphate rock of various ages in the Rocky Mountains of British Columbia. The Kapuskasing Phosphate Operations, Canada's first-ever phosphate mine, ranks as one of the highest-grade phosphate mines in the world. Located in the Cargill Township about 40 km southwest of Kapuskasing, this mine has been developed to supply high-quality, low-cost phosphate rock to Agrium's facility in Redwater, Alberta.

According to Pressacco (2004), the local geology consists of a core complex of multiphased carbonatite rocks that are surrounded by a ring of pyroxenite. These two rock types are in turn situated within quartz diorite gneisses that form a large portion of the Kapuskasing structural zone. The carbonatite host rock is subdivided into sovite and rauhaugite. The sovite is a medium to coarse grained, white, banded rock in which calcite is the dominant carbonate species. Sovite includes accessory minerals such as phlogopite, magnetite, clinohumite, apatite, olivine, pyrrhotite, and amphibole. Apatite can reach 15% abundance in this rock type (Sage 1988). In contrast to the sovite, the rauhaugite appears as a massive, fine-grained, dense rock, beige or tan in color, in which dolomite is the dominant carbonate species. Phosphate values in the rauhaugite can reach 14% (Pressacco 2004).

The high-grade ore at the Kapuskasing Phosphate Operations is derived from the weathering and dissolution of the soluble minerals in the host carbonatite rock (e.g., phlogopite). This process has left behind a residue of the insoluble minerals, largely apatite crystals, which is termed *residuum*. This residuum forms above the host carbonatite, and is in turn covered by glacial deposits of lacustrine clays and boulder tills of the Pleistocene age. Limited data suggest that this weathering took place during the late Cretaceous period.

Mexico

The major phosphate resources in Mexico are the Miocene phosphate deposits of Baja California. Roca Fosforica Mexicana SA de CV (Rofomex) started up one phosphate mine in Baja California Sur in 1981 and another in 1982. The combined production of these operations was expected to lift Mexico from a position of almost total dependence on phosphate rock imports in 1980 to self-sufficiency in 1985. That goal has not yet been achieved: Mexico still imports about 200,000 tpy of phosphate fertilizer.

The first of the new Rofomex mines is located at San Juan de la Costa on the Gulf of California. It produced its first concentrates in January 1980. The design capacity of the San Juan de la Costa mine is 730,000 tpy of concentrates grading about 31% P_2O_5 from combined open-pit and underground mining operations that extract ores grading 18% P_2O_5 . At Santo Domingo, on the Pacific shore of the Baja California peninsula, Rofomex constructed a mine that could produce 1.5 Mtpy of concentrates by dredge mining a beach sand deposit that grades about 4.5% P_2O_5 at a cut off grade of 3% P_2O_5 .

Figure 2. Distribution of phosphate deposits in Florida

Over the long run, Mexico has a substantial phosphate resource to draw on in Baja California Sur, a part from the two deposits being developed. Other phosphate occurrences are located at San Hilario, Santa Rita, Tembabiiche, La Purisima, San Jose de Castro, and San Roque. Of these, the deposit at San Hilario has been the most extensively explored, with drill indications of substantial rock tonnages grading 11% to 13% in weathered cap rock and 14% to 18% in unweathered rock under 30 to 80 m of overburden. In the Santa Rita area, possible economic concentrations of phosphates occur in recent sediments under almost no overburden, but these remain to be more intensively explored.

United States

Florida. The phosphate deposits in Florida fall under three major categories: land pebble, river pebble, and hard rock (Figure 2). The river pebble has long been mined out, and hard-rock mining ceased 40 years ago. Current mining activities are concentrated on two of the largest land pebble deposits, the Bone Valley and Hawthorn formations. The Bone Valley Formation is of Pliocene age, covering six counties in central Florida, roughly 60 mi (97 km) long and 30 mi (48 km) wide. Although this formation was known as one of the richest phosphate deposits in the world, the high-grade ore (matrix) has been almost depleted, with some mines processing flotation feed analyzing as low as 3% P_2O_5 . As a matter of fact, most phosphate ores in central Florida are being extracted from the southern extension of the Bone Valley deposit. As is shown in Table 7, phosphate matrix in the southern extension can be divided into an upper zone and a lower zone (El-Shall and Bogan 1994). The lower zone is highly contaminated by dolomite (Table 8).

Table 7. Analysis of central Florida phosphate matrix

Upper Zone

* BPL = bone phosphate of lime (derived by multiplying percent P₂O₅ by 2.185).

Table 8. Average chemical analyses—pebble fractions, wt %

Zone	P ₂ O ₅	CaO	MgO	Fe ₂ O ₃	Al ₂ O ₃	Na ₂ O	F	Insol
Upper	27.8	41.8	0.52	1.10	0.99	0.57	3.50	12.0
Lower	17.0	35.8	6.19	1.30	0.80	0.43	2.10	13.90

The Hawthorn Formation, on the other hand, is of Miocene age. The upper unit of this formation is similar to the Bone Valley Formation in terms of main mineral components. This deposit is roughly one third the area of the Central Florida deposits, but much less in total tonnage.

Today, five companies mine or process phosphate in Florida: Cargill Crop Nutrition, CF Industries, IMC Phosphates, PCS Phosphate, and U.S. Agri-Chemicals.

North Carolina. In the late 1950s, a phosphate deposit was found beneath a large portion of Beaufort County in the Miocene Pungo River Formation. Subsequent exploration delineated a mineable ore body that contained about 2 billion tons of phosphate ore. North Carolina deposits lie beneath strata ranging in thickness from 13.6 to 75.8 m. The P₂O₅ content varies from 2% to 21%. Reserves in the Beaufort County area are among the largest in the United States, constituting 1,813 km² of phosphate deposits. North Carolina is now the second-leading phosphate producer behind Florida. The phosphate is produced by Potash Corporation of Saskatchewan, which purchased the assets of Texasgulf, Incorporated, in 1985. Phosphate production is from the large open-pit Lee Creek mine near Aurora in Beaufort County. The major portion of the output from this mine is used in nearby chemical facilities to produce phosphoric acid, TSP, and DAP. Deposits of phosphorite also occur off North Carolina's coast in the northeast Onslow Bay District and the Frying Pan Shoals District. The lower part of the Pliocene Yorktown Formation contains phosphorite in the Aurora phosphate district and represents a potential resource. Further exploration may lead to production from these deposits.

Western States. The Permian sediments of Montana, Utah, Wyoming, and Idaho cover about 350,000 km². These reserves are estimated to total 1.6 billion tons at 24% P₂O₅, and constitute about 30% of U.S. reserves and 3% of the world total.

Mining can be traced back to 1904, when an underground operation near Montpelier, Idaho, was started. Large-scale phosphate mining began in 1921 by Anaconda Co. in Conda, Idaho.

J.R. Simplot entered in 1946 by opening the Gay open-pit mine on Fort Hall Indian Reservation, 50 km north east of Pocatello,

Idaho. The Smoky Canyon mine was developed in the mid-1980s. In 1992, the Gay mine was closed.

The phosphate mining industry in Idaho has a unique economic advantage compared with other hard-rock mining in the state and phosphate mining in the United States in general, perhaps because of its proximity to some domestic markets and low production costs. Idaho production of phosphates accounts for more than 12% of the national production. Currently four open-pit operations produce more than 5 Mtpy of ore. The mines deliver ore to two fertilizer plants and two elemental phosphate plants. All four sites are reportedly experiencing selenium releases associated with their waste dumps (Blanchard et al. 2002). These mines are Astaris's Dry Valley mine, J.R. Simplot's Smoky Canyon mine, P4 Production's Enoch Valley mine, and NuWest's Rasmussen Ridge mine.

Today five companies mine or process phosphate in Idaho: J.R. Simplot Company, Monsanto, Rhodia, NuWest Industries (Agrum), and Astaris (formerly FMC).

Phosphate rock processing at Vernal, Utah, began in 1961. J.R. Simplot recently acquired this operation. The ore consists of a hard-rock sedimentary stratum of the Phosphoria Formation of Permian age. The ore is covered by up to about 30 m of overburden, comprising Lower Franson limestone (10 m), Mackentyre shale (10 m), and Upper Franson limestone (10 m), and rests on the Weber sandstone. Exploration drill holes indicate ore thickness of 4 to 6 m, assaying 16% to 22% P₂O₅ and 1.9% to 3.3% MgO. The ore minerals have been identified as collophane, dahllite, and francolite, all carbonate-apatite minerals. Collophane is the most abundant, occurring as pellets of 75 to 500 µm, averaging 150 µm. Pellets are cemented with calcite and dolomite with some chert, clay, and massive collophane. Local fracturing and faulting facilitated weathering. Oxidation of the minor amounts of sulfides in the ore attacked and weathered the carbonate cement, so the weathered ore is easier to grind (Allen 1993).

Brazil

Brazil is the only significant phosphate rock producer on the South American continent. The Brazilian phosphate deposits are of igneous

nature, accounting for 2.6% of the estimated worldwide reserves. The extensive mineral prospecting from 1975 to 1985 nearly tripled the Brazilian rock phosphate deposits. Phosphate production during that period also saw its highest increase (1,207%). Most (87%) of phosphate deposits in Brazil are in the Cerrado region, which covers eight provinces.

One of the largest mines in the Cerrado region is the Tapira mine in the northern portion of the Tapira ultramafic alkaline-carbonatitic complex, in the west of Minas Gerais state (southeastern Brazil). Known reserves of this deposit are about 1.2 billion tons, with an average grade of 8.2% P_2O_5 .

Peru

Peru has one of the 10 largest phosphate deposits in the world, the Bayovar deposit, which is about 1,000 km north of Lima in the Sechura Desert. It has reserves of more than 800 Mt. Except for a pilot-plant operation, this deposit has remained untapped since its discovery, mainly because of the lack of infrastructure in this remote desert area. The government of Peru reannounced the auction of the Bayovar phosphate deposit in December 2000, after several postponements over the past years. The government hoped to gain US\$600 million in proceeds from the privatization of the property. Firms that were listed as being interested in acquiring the property include 65 companies, among which are IMC Global Inc.; Oswal Chemicals & Fertilizers Ltd. of India; FOSKOR of South Africa; Jua Paulo Quay of Spain; and Hermasa E. Interocea, Ipiranga, and Serrana, all of Brazil.

Africa

Morocco. Morocco not only has the world's largest phosphate reserve base but also enjoys high-grade, easy-to-process deposits. The deposits, all sedimentary, were first discovered in 1908. In 1920, the Office Cherifien des Phosphates (OCP), a government organization, was created for exploitation and sale of phosphate rock. The first phosphate rock was produced in 1922. Since then, OCP steadily increased production, reaching 1 Mt in 1939 and the current level of more than 20 Mtpy.

The Moroccan phosphorite resources are hosted in late Cretaceous, Palaeocene, and Eocene marine sediments. Sequences comprising clays, marls, li mestones, and che rts contain several phosphate-rich beds. OCP currently operates four operations, as shown on Figure 3. Morocco is also moving toward increasing exports of processed phosphate. Its phosphate fertilizer exports increased from less than 10 0,000 tpy during the 1970s to the current level of more than 1 Mt, and phosphoric acid exports more than tripled from 1990 (631,800 t) to 2000 (1,547,800 t).

Western Sahara. Since the "liberation" of the former Spanish Sahara by Morocco in 1975, phosphate mining in this region has been under the auspices of OCP. The Bou Craâ deposits were estimated to be about 1,600 Mt, with half the reserve containing 31% P_2O_5 .

Tunisia. Tunisia is the second largest phosphate producer in Africa, turning out about 8 Mt of rock on average in recent years. The phosphate deposits of Tunisia are all sediments, ranging in age from Maastrichtian to Lutetian, found in the Metiaoui Formation in the southern part of the Tunis Basin. Two distinct deposits compose the sediments in this basin—the anticlinal deposits of the Gafsa region and the perched synclinal deposits of the Tebessa-Thala region. More than 90% of the phosphate rocks are currently mined from the Gafsa region. Another potentially important region is represented by the Thanetian phosphate beds, east of Gafsa. Approximately 500 Mt of Tunisian phosphate rock are currently classified

Adapted from Mining-Technology.com 2004.

Figure 3. Locations of major phosphate deposits in Morocco

as mineable. Figure 4 shows where most of the phosphate deposits are located, with circled hammers indicating mining operations.

Algeria. The most important phosphate deposit in Algeria is the westward extension of the Tunisian Gafsa Basin, which is shown in Figure 4. With a resource of about 1,000 Mt and the current mining rate of about 1 Mtpy, Algeria certainly has the potential to produce phosphate for many years to come.

Egypt. The three major phosphate deposits in Egypt are located near the Red Sea, in the Nile Valley, and in the Western Desert. These are all sedimentary, medium grade (20% to 28% P_2O_5), with a total reserve base of 760 Mt. The current phosphate rock production from a few mines averages about 1.5 Mt.

Senegal. Sedimentary phosphate rock occurs at several areas in Senegal. Most of the high-grade deposits are concentrated in the west. Senegal is blessed with extensive reserves of exceptionally high quality phosphate. Marketable phosphate from Taïba (with a standard of 79 BPL), which has been mined since 1960 in Ndomor Diop and more recently in Keur Mor Fall, is famous around the world. The phosphate ore is buried under a layer of sand 30 to 40 m deep. The thickness of the ore seam is between 7 and 10 m. The ore is made up of marketable phosphate, sand, clay, or mud and flint.

Togo. Since the beginning of large-scale mining of phosphate deposits at Akoumpe (in the southeast) in 1963, phosphate mining has become Togo's most important industry, with an annual production of more than 2 Mt. The phosphate beds vary in thickness from 2 to 6 m, while the overburden of sand and clay ranges from 7 to 30 m. The two phosphate mines in Togo produce one of the highest grade phosphate rocks, analyzing 36% P_2O_5 with minimal amount of Mg, Al, and Fe.

South Africa. Though not as famous as its gold and diamond mining industries, South Africa's phosphate mining industry has met domestic needs for phosphate plus some exports for quite

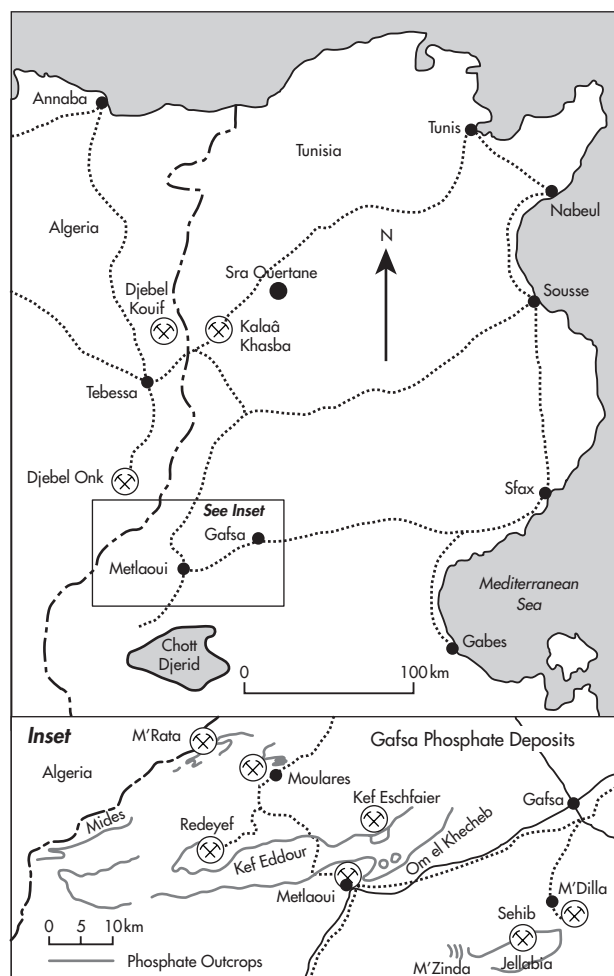

Figure 4. The Gafsa phosphate deposits in Tunisia

some time and may play an important role in the international market in the future, because its phosphate reserve base ranks fourth in the world. The majority of South Africa's phosphate deposits are of igneous nature. The deposits are generally of low to medium grade with high Fe and Al contents. Figure 5 shows the most important phosphate complex operated by Foskor. The Palabora deposit, in northern South Africa, was originally exploited as a source of copper and iron in the seventeenth century by a tribal group of the Monomotapa Empire that wandered south from Central Africa. The associated phosphate resource was commercially mined in the early 1930s by South Africa Phosphates, Ltd., which mined high-grade apatite pockets and sold this as a fertilizer product but soon went bankrupt because of the less expensive Moroccan phosphate rock imports. The state acquired claims and leases and a company, which became known as Phosphate Development Corporation, Ltd., and eventually Foskor, Ltd., and began mining in the early 1950s. Gradually the fertilizer producers adapted their processes to the use of the igneous phosphate rock produced, and in 1976 a significant expansion enabled production for an export capability. At present, approximately one third of the phosphate rock is used domestically, one third is exported as rock, and the remainder is acidulated for phosphoric acid and fertilizer ingredients for export.

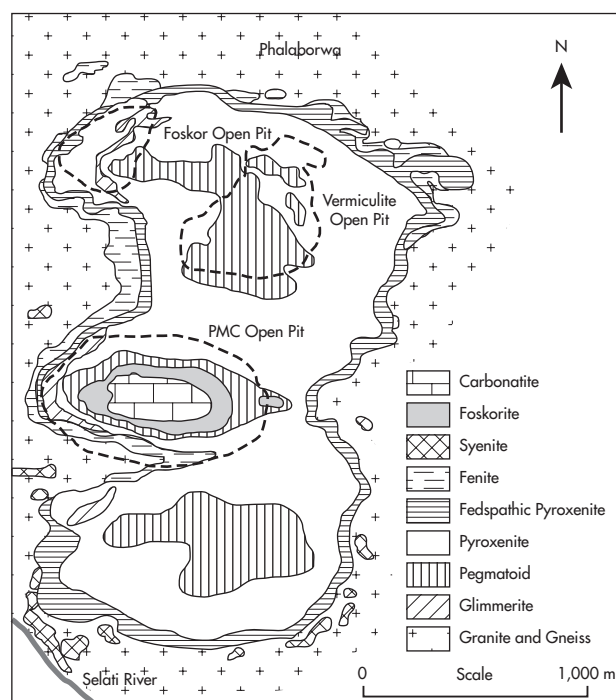

Figure 5. The Igneous Phosphate Complex in South Africa

Middle East

Israel

Nearly all phosphate deposits in Israel are located in the Negev Desert. Substantial resources of phosphate rock occur in the northern Negev region. Arad-Rotem, which was the largest deposit, has 300 Mt, and the Zohar, Zin, and Arava deposits have 250 Mt, 150 Mt, and 150 Mt, respectively. These deposits are associated with flint beds in shallow water sediments, with the phosphorite horizon ranging up to 20 m. The main mineral constituents are francolite and calcite, with small amounts of gypsum, clay, quartz, iron oxides, halite, and dolomite. Israel mines more phosphate than it can consume domestically and exports phosphoric acid to India, Italy, and Turkey, and phosphate rock to Brazil (about 42%), France, Ireland, Italy, the Netherlands, Spain, and the United Kingdom.

Jordan

It may not be exaggerating to say that phosphate deposits can be found anywhere in Jordan. Phosphate deposits are Jordan's primary natural resource and a major source of export income. Estimates of Jordan's proven, indicated, and probable reserves range from 1.5 billion to 2.5 billion tons. Conservatively speaking, Jordan could produce phosphate at its present rate for hundreds of years. In recent years, Jordan produced about 7 Mtpy of phosphate rock, a majority (about 85%) of which was exported as raw rock. In 1985, the Jordan Phosphate Mines Company closed the country's original phosphate mine at Ar-Rusayfah near Amman because of declining rock grade. This left major phosphate mines in operation at Al Hasa and Wadi Abu Ubaydah near Al Qatranah in central Jordan, and a new high-grade mine at Ash Shidiyah, 40 km south of Maan. Reserves at the new mine were estimated to be more than 1 billion tons. The principal phosphate deposits in Jordan are sedimentary type, ranging in age from Campanian to Eocene.

Figure 6. Map showing Hubei, Guizhou, Hunan, Sichuan, and Yunnan provinces, which have major phosphate occurrences

Saudi Arabia

Saudi Arabia is a “sleeping giant” in terms of phosphate mining potential in the Middle East, with phosphate resources estimated up to 3,000 Mt averaging 18% to 21% P_2O_5 . The largest phosphate formation is the Sirhan-Turayf sedimentary deposit, which extends into Jordan, southern Iraq, and Syria. The best explored and largest deposit is at Al Jalamid, which has measured reserves of 213 Mt averaging 21% P_2O_5 and a stripping ratio of 2.3:1. Indicated resources amount to a further 187 Mt, with 19.7% P_2O_5 and stripping ratios of 5:1 or less. The second important deposit is in the Umm Wu’al North Area with a total resource of 537 Mt averaging 19.35% P_2O_5 with a stripping ratio less than 5:1.

Syria

Syria is another Middle Eastern country with a significant phosphate reserve, nearly 800 Mt. Most of the potentially economic deposits are located in the central part of the country. The richest deposits analyze 31% to 34% P_2O_5 . Phosphate mining started in 1971, and production has reached about 2.5 Mtpy.

Asia

China

China’s phosphate deposits are all over the map with more than 250 areas (Figure 6). The five major formations, in Hubei, Guizhou, Hunan, Sichuan, and Yunnan provinces, account for 75 % of

China’s phosphate reserve. The Wengfu phosphorite deposit located in central Guizhou province is a super large ore deposit occurring in Late Sinian (Latest Precambrian) rock. The phosphorites are hosted in the Doushantuo Formation. In ascending order, the Doushantuo Formation can be divided into four members: a “bottom bed,” mainly dolostones; a “lower ore bed” of phosphorites; an “interbed” with dolostones and cherts; and an “upper ore bed” of phosphorites. In the Kunming Area of Yunnan Province, the main phosphate ore horizon is the Upper Phosphorite averaging 5.8 m, which is made up of dolomitic, fine grained, and siliceous phosphates. The siliceous portion does not require complicated beneficiation and is of high grade. There are three major phosphate beds in the lower Doushantuo Formation, a significant portion of which contains 5% to 8% MgO.

Mongolia

There are two phosphate reserve basins in Mongolia. The first area, the Khulosgul basin, was discovered in the north of the country by geological exploration work from 1963 through 1986. The Zabkhan phosphate basin was discovered in the west of the country from 1987 to 1997 (Dorjpalam and Amgalan 1998). As the result of a broad geological exploration work in Mongolia since 1963, more than 50 deposits have been discovered in the two basins, with estimated total reserve base of approximately 5.7 billion tons. If this is true, Mongolia would be placed second in Asia

in terms of reserves. The KPB phosphate basin covers 30,000 km² and has an estimated reserve of 4.5 billion t. Some of these phosphate deposits are excellent in grade, analyzing over 30% P₂O₅. Mg content, however, is high in most of the ores.

Because of the lack of infrastructure and environmental concerns, phosphate mining in Mongolia may not happen in the near future.

India

The use of phosphatic fertilizers in India has maintained a steady upward trend. The current annual domestic demand of apatite and rock phosphate is about 4 Mt, with domestic production meeting hardly 35% of the total demand. This trend will not change dramatically, because India's phosphate reserve is disproportionately small. The inadequate phosphate resources, together with insufficient capacity to beneficiate the low-grade phosphate ores, will force the country to depend more and more on imported high-grade rock phosphate.

The major phosphate deposits in India are of sedimentary origin, concentrated in two formations—the Precambrian Aravalli Formation and the Jurassic Lower Tal Formation. The former is of better quality, located in Rajasthan, Madhya Pradesh, and Uttar Pradesh. A significant portion of these deposits analyze over 30% P₂O₅.

Oceania

Australia

After years of staying nearly dormant, phosphate mining in Australia has revived in recent years. The original phosphate rock deposits owned by Western Mining Corporation Ltd. (WMC), which underpin the current operations, were initially discovered by Broken Hill South Pty Ltd. in 1966 in northwestern Queensland.

By 1978, after investment of over seventy million dollars in the mine, rail and port infrastructure, export of rock proved unprofitable due to a number of reasons including production difficulties, removal of the Australian superphosphate bounty and the failure to secure long term contracts. This resulted in the closure of mining operations and the collapse of Broken Hill South (Osborne 2001, p. 2).

In 1980, WMC acquired a major interest in Queensland Phosphate Limited and its phosphate rock reserves 130 km south of Mount Isa. The resource is an 11-m-thick deposit of approximately 2 billion tons of sedimentary phosphate rock. This deposit is close to the surface and easily extracted using open-cut mining. Having recognized that to achieve an acceptable return on investment the phosphate rock would have to be converted into either granulated TSP or ammonium phosphates, WMC decided to invest in a facility for manufacture of ammonium phosphates. This proved to be a profitable proposition and placed Australia back on the map of the world's major phosphate producers.

Nauru

Phosphate deposits occupy about 90% of the island of Nauru. These deposits are of the highest grade, with the run-of-mine ore analyzing to 40% P₂O₅. Nauru once possessed the highest GDP per capita in the world because of its rich phosphate deposits, which have been nearly depleted.

Europe

Russia

Once the world's largest phosphate producer, Russia is now ranked fourth, falling behind the United States, Morocco, and China. Both

Figure 7. Phosphate distribution in the former U.S.S.R.

sedimentary and igneous phosphate deposits are widespread in Russia. The most important igneous deposit is the Khibiny Complex in the Kola Peninsula, with the Kovdor Complex bordered by Finland being the only other significant igneous deposit. Mines at the Khibiny Complex have a combined capacity of 20 Mtpy. Phosphate ore averaging 17% P₂O₅ is upgraded to almost 39% P₂O₅ using flotation technology. At the Kovdor Complex bordering Finland, the igneous phosphate is a secondary product from iron ore mining. Electromagnetic processing of the iron ore results in tailings analyzing about 30% P₂O₅ and 4.5% MgO.

The largest sedimentary phosphate deposit in this region is the Kara Tau Basin with a resource of about 8,000 Mt averaging 21% P₂O₅. In early mining, phosphate ore was crushed, ball milled, and screened to obtain a product of 23% P₂O₅ for elemental phosphorus manufacture. Other major sedimentary deposits are located along the southern margins of the Moscow Basin (Figure 7).

Finland

Finland is the only European country other than Russia that is currently mining phosphate. The only economically important deposit is the Siilinjärvi igneous deposit.

TECHNOLOGY

Mining

Surface Mining—Dragline

At present, most phosphate rock is mined using large-scale surface methods. In the past, underground mining methods played a greater role, but their contribution to world production has declined. For example, in Idaho, phosphate mining has been transformed from 100% underground during the 1930s to nearly all surface mining

today. Phosphate rock surface-mining operations can vary greatly in size. Extraction may range from several thousand to more than 10 Mt of ore per year. In many cases, operations supply feed to a nearby fertilizer-processing complex for the production of downstream concentrated fertilizer products. The land area affected by the surface operations can vary widely, depending on the ore body geometry and thickness. At similar extraction rates, mining of flat-lying, thin ore bodies as found in Florida will affect a far wider area of land than the mining of thicker ore bodies as found in Brazil and Idaho. The depth of excavations may range from a few meters to more than 100 m. Currently, most phosphate rock production worldwide is extracted using opencast dragline or open-pit shovel/excavator mining methods. This method is employed widely in parts of the United States, Morocco, and Russia. Underground mining methods are currently used in Tunisia, Morocco, Mexico, and India.

Surface Mining—Drilling and Blasting

In Khouribga, Morocco, the 16- to 17-m-thick overburden is drilled, blasted, and removed by dragline to the side of the mining area for subsequent reclamation. Small draglines, electric shovels, and bulldozers recover the upper ore body. The intercalating limestone layer is then blasted and removed to expose the Bed I phosphate, which is loaded onto trucks. The process is repeated to mine the Bed II phosphate deposit.

At Vernal, Utah, mining begins with tractor removal of topsoil and temporary storage for reclamation. Overburden is drilled and blasted with ammonium nitrate and fuel oil and shoved into mined-out areas. The ore is then drilled, blasted, and loaded by shovel into trucks for transport to a feeder-breaker. The broken product at 25 cm is conveyed by belt to a 10,000-t live storage pile. Mining is conducted 5 days a week, in two 8-hour shifts per day. Overburden in mined areas is contoured, covered with topsoil, and seeded.

Dredge Mining

Consideration of mining systems for the Santo Domingo, Mexico, project included bucketwheel excavators, draglines, scrapers, shovels, and dredges. Selection of a dredge-based system was favored primarily on the basis that the other systems could not operate effectively below sea level. Low operating and maintenance costs prompted the final selection of floating hydraulic cutter suction dredges with 27-in.-diameter suction heads. Two Ellicott dredges were used, each capable of pumping about 2,000 tph of slurried solids to the floating primary beneficiation plant.

Dredge mining was also practiced at the Wingate Creek mine in central Florida, which ceased operation in 1999.

HAULAGE

The three major methods of hauling materials in phosphate mining are pumping, trucking, and transporting using conveyor belts. In the United States, pumping is the predominant means of moving ore and tailings, with the longest pipeline running 87 miles, via which J.R. Simplot transports phosphate rock slurry from its Smoky Canyon mine in Wyoming to Pocatello, Idaho.

PROCESSING/BENEFICIATION

Washing and Sizing

Florida (United States)—Washing

The coarsest portion of the disaggregated matrix (+50 μm) is removed to waste by trommel screens, because it usually represents lower phosphate grade and is likely to contain significant dolomite-cemented conglomerates. At one time this coarse material was broken in hammer mills to pebble size, but this is now avoided because of the grade and dolomite contamination problem. As the mining

moves to the south or west, the portion of phosphate rock product produced in the washer by disaggregation and simple screening is expected to diminish from the roughly 50% for the Bone Valley to about 20%. Because pebble production is relatively inexpensive, the reduction of this production has an unfavorable impact on costs.

The disaggregation, which largely takes place in the pumps and transport lines, is completed by log washing at high percent solids to scrub residual clay from the mineral surface and wash it countercurrently away from the rock. Vibrating, plastic-coated screen decks permit the final removal of the pebble (+1 mm) from the flotation feed (−1 to +50 μm), which is suspended in a dispersed clay (−50 μm) slurry.

The coarser washer pebbles still contain large amounts of dolomite, and therefore at some mines this coarse pebble (+20 mm) is scalped from the product and treated as waste. Two Florida mines installed heavy media hydrocyclone plants to reduce the dolomite contained in the pebble. The density separation is enhanced by the relatively high porosity of the dolomite compared to the francolite. These heavy media plants have not been operated since the early 1990s because the local chemical plants have learned to accept higher dolomite levels and the miners have learned to avoid high dolomite pebble areas by selective mining. Unfortunately, this does deplete the reserve base for continued mining activity.

Florida (United States)—Desliming

The slurry containing flotation feed and clays, which represents the combination of pebble screen undersize, log washer overflow, and most other slurry streams created in the washer, is pumped through two stages of hydrocyclones with recycled water added to the first hydrocyclone underflow for dilution. This removes roughly 98% of the fine suspended clay particles from the flotation feed but creates a clay slurry waste containing 4% to 6% solids, which by themselves settle very slowly in clay ponds. Because roughly 30% to 40% of the mined material weight is clay, these ponds represent a very substantial capital investment in terms of both construction and reclamation when filled. These ponds also act as reservoirs for water recovery and recirculation. Some plants installed the facilities required to accelerate the clay settling by flocculation using high-molecular-weight anionic flocculants. There is of course concern about the chemical quality of the recycled water removed by flocculation, but some companies believe the capital and operating costs for operating clay ponds and handling the large volumes of clay slurry exceed the cost for flocculants and any additional flotation reagents or loss of phosphate recovery incurred.

Florida (United States)—Sizing

Most phosphate flotation plants separate the flotation feed (−1 mm to +50 μm) into at least two size fractions with the split point at about 420 μm or 35 mesh. There is ever-increasing evidence of economic and metallurgical benefit to be gained by this practice. High-capacity hydraulic sizing units have been used in the industry since the mid-1980s; these provide sharper size separations than the previously used multiple stages of inclined profile wire screens. The hydraulic sizer overflow, when separating at 420 μm , contains roughly 80% of the flotation feed solids weight, whereas the underflow at about 50% solids is of such a volume that it can be more readily handled by high-speed vibrating screens. There are usually three or four products from the combination of hydraulic and screen sizing. The finest fraction, from 105 to 420 μm or passing 35 mesh, is termed *fine flotation feed* and represents about 80% of the flotation feed weight and would be the hydraulic sizer overflow. The next finer fraction, from 420 to 595 μm , is called *coarse feed* and represents about 10% to 15% of flotation feed weight and would be

a vibrating screen undersize. If there is a third flotation feed, it would be roughly from 595 to 1,000 μm and represent 5% to 10% of the flotation feed weight. In the past, this third fraction was treated by several flotation techniques such as using shallow belt flotation or flotation on spirals. Today, although consideration has been given to the use of column flotation to upgrade this stream, many plants combine this product with the final sizer vibrating screen oversize and treat this as a lower grade pebble product. In years past, the final sizer vibrating screen oversize would represent misplaced pebble and coarse flotation feed and would be recirculated to the washer for retreatment.

Australia

WMC Fertilizers, a subsidiary of the Melbourne-based WMC, recently put into operation their phosphate complex in Northern Queensland in Australia. This new facility includes a mine, a beneficiation plant, wet process phosphoric acid manufacture, an ammonia plant, and a DAP/MAP granulation plant. Sulfuric acid used in acidulating phosphate rock is manufactured from the off-gases generated by the M.I.M. Holdings Ltd. copper smelter plant about 150 km from the fertilizer production facility. The phosphate used at this facility is of a very low grade compared to other sedimentary deposits, with an average grade of only 23.5% P_2O_5 . The main impurity is silica, which makes up about one third of the ore. The only beneficiation of the ore is water scrubbing to remove fine clays.

Togo

In Togo operations, the phosphate ore is first scrubbed with seawater, then wet screened at between 0.8 and 3 mm, depending on the quality of the ore. The clay is then removed using hydrocyclones. The high ferrous product is further dried and upgraded using electromagnetic separation technology.

Jordan

JPMC is currently operating three open-pit mines: El-Hassa, El-Abiad, and Eshidiya. The company started production in the 1930s from the Ruseifa mine, 17 km north of Amman. In the 1960s, the mining operation moved to the south, where production started from the El-Hassa mine, 136 km south of Amman and 200 km north of Aqaba port. In the late seventies, production started from the El-Abiad mine, about 20 km north of El-Hassa mine. In early 1988, production started from the Eshidiya mine, which hosts the largest high-grade reserve in Jordan.

In most operations, phosphate ore is first crushed and screened to reject the 12.7-mm material. When the 12.7-mm fraction makes the grade of 66% to 68% BPL, it is directly fed to rotary cascading dryers to produce a final product. The lower grade ore requires beneficiation, which involves sizing and desliming at about 200 mesh using hydrocyclones.

Morocco—Yousseoufia

The Yousseoufia zone is the western part of the Gantour deposit. Only underground mining is practiced at this mine. This location has proven reserves up to 7.7 billion m^3 . Annual mining capability is 2 Mt of merchant-grade phosphate rock. Here, the high-grade “white” phosphate is simply dried and shipped, and the “brown” phosphate is calcined (at $>700^\circ\text{C}$) to eliminate organic matter.

Morocco—Benguerir

Located 70 km north of Marrakesh, Benguerir is the newest of Morocco's four phosphate mining centers operated by OCP. Beneficiation at this location is very simple, by first removing +100 mm

material, followed by crushing and sizing at 10 mm, with the +10-mm material rejected.

Morocco—Khouribga

Located 120 km southeast of Casablanca, Khouribga is the largest phosphate mining zone operated by OCP Group. The phosphate deposit is of sedimentary origin, with several phosphate-bearing layers alternating with layers of marl and limestone. Phosphate reserves are estimated at more than 35 billion m^3 . Production of phosphate rock started in March 1921 by underground mining. Open-pit mining was introduced in 1951, and was replaced by underground mining by 1994. High-grade ore is screened and stored, and low-grade ore is treated using log washers and hydrocyclones. Calcination is also used at this location to treat the lower grade ore.

Morocco—Bou Craâ

Beneficiation of this Saharan phosphate is also fairly simple. The ore is crushed and slurried with seawater. Unwanted materials are removed by sizing and desliming.

Crago Double Float Process

The Crago double float process has been practiced in Florida for more than half a century. Modified versions or part of the process are also practiced in other parts of the world. This process is particularly suitable for processing siliceous phosphates, where low-silica product is required. The desliming and sizing steps are described in details in the Washing and Sizing section in this chapter and are shown in Figure 8.

The flotation plant consists of a number of important processing steps:

1. The removal of flotation feed at a controlled rate from partially consolidated storage bins
2. High solids conditioning of the solids (60% to 65%) with a pH modulator and anionic flotation reagents, namely a vegetable-derived fatty acid as a collector, a petroleum extender, and sometimes surfactants to impart desirable selectivity or frothing characteristics
3. Dilution with clean, recirculated water to roughly 20% solids for the rougher flotation step of the bulk of the phosphate mineral from the sand
4. Collection of the froth concentrate and scrubbing of the solids with sufficient sulfuric acid to free the fatty acid and fuel oil coating, followed by rinsing and dewatering with clean, recycled water to provide a clean mineral surface for further separation
5. Dilution with either fresh or very clean recycled water, adjustment of the pH to approximately neutral, and addition of a cationic flotation reagent (an amine, a light petroleum extender, and sometimes a surfactant) into a mixing tank or the feed box of the flotation cells; this cleaning flotation step is aimed at removing any fine sand inadvertently carried into the rougher concentrate by the relatively high reagent levels required to float the phosphate mineral
6. Partial dewatering of the cleaner cell underflow concentrate and holding in bins until routed to appropriate storage pile locations when chemical assays are available
7. Combining of the cell underflow tailing product from rougher flotation and the froth tailing product from cleaner flotation to create a combined tailing that is pumped to reclamation areas for landfilling in the mine.

water and permits the return of a reasonably clean recycle to the flotation plant. The additional water required to achieve a balance is obtained from rainwater collected in the mine, plant, and pond areas that is diverted to the ponds for storage. Some groundwater is extracted for special uses such as for pump seals, but it is carefully monitored to avoid exceeding permit limitations. Overall, approximately 95% of the water used is recycled.

A recent study of the fate of the relatively large amounts of consumed flotation reagents (Patel and Ben-Poorat 1999; Patel, Powers, and Zhang 1999) indicates no reason for concern over environmental consequences.

Anionic Flotation Only

Senegal

In Senegal operations, after desliming and sizing, the phosphate is upgraded using a fatty acid tall oil. The silica and the iron and aluminum oxides are depressed and a high-grade concentrate analyzing up to 80% BPL is produced.

South Africa

Foskor of South Africa produces phosphate rock from three sources, namely pyroxenite ore, foskorite ore, and PMC tailings. The pyroxenite ore is crushed and milled to 15% +425 μm and 20% –74 μm . The mill product is pumped to conditioners from which it flows to the flotation circuit, where apatite is floated using Wemco flotation cells. Flotation is done in a four-stage flotation circuit comprising rougher, scavenger, cleaner, and re-cleaner stages, with the recirculation of middlings. The pyroxenite process with only two reagents in the system is relatively simple and hardly ever gives any trouble. A straight-chain petroleum sulphonate or sulphonic acid and a tall oil fatty acid are added to the pulp at the conditioners. From ore with a head grade of 7% P_2O_5 , a concentrate with a P_2O_5 content of 39.6% is produced with a recovery of 70% (Coetzee, Visser, and Mehrliss 1976; Lovell 1976).

In the circuit for foskorite, flotation is also done in a four-stage flotation circuit comprising rougher, scavenger, cleaner, and re-cleaner stages, with recirculation of middlings, using Wemco flotation cells. Three reagents are used: sodium silicate ($\text{Na}_2\text{O} \cdot \text{SiO}_2$) as a dispersant; nonyl phenyl tetraglycol ether as a modifier and depressant; and a tall oil fatty acid as a collector. The average head grade of the foskorite is 7.5% P_2O_5 , whereas the concentrate grade is 38.5% P_2O_5 with a recovery of 67%.

PMC mines and processes the central carbonatite plug and the surrounding foskorite ore separately. The carbonatite contains an average of 3.5% P_2O_5 . After PMC extracts the copper and the magnetite from the ore, the slurry is pumped to Foskor. The PMC tailings stream is deslimed using two-stage cyclones, which remove 85% to 90% of the –12- μm slime fraction. PMC tailings, being a foskorite ore, are treated in the same way as the normal foskorite ore. In addition to the flotation reagents used for the foskorite circuit, a polysaccharide is used mainly as a depressant. Polysaccharides that have been used successfully include gum arabic and guar gum.

Russia

In Russia, a majority of the phosphate rock is turned out from the phosphate mines at the central Kola Peninsula. The mines are about half open pit and half underground. Phosphate ore is first crushed to –20 mm before being sent to the beneficiation plant. In the beneficiation plant, the feed is ground to approximately 55% passing 74 μm . Anionic rougher flotation is followed by several stages of cleaning and scavenging flotation. The output is more than 9 Mtpy

(10 million stpy) of concentrates with a P_2O_5 grade of 39% from an ore assaying 18% P_2O_5 , 23.1% SiO_2 , and 13.3% Al_2O_3 in a bonded phase of nepheline-syenites.

Jordan

In Jordan, direct flotation is used where the phosphatic elements are floated by an ionic flotation, using an aqueous blend of tall oil and diesel oil as phosphate collector, sodium silicate as clay dispersant, and silica depressant for both fine and coarse fractions, with several roughing and cleaning stages.

Brazil

The Brazilian apatites also represent an important source of igneous phosphate ores. They are included in carbonatites (with simple carbonates as in Jacupiranga or as more complex ones with iron carbonates, phlogopite or vermiculite, titanium minerals, barytine, pyrochlore, etc.). The P_2O_5 contents are comparatively low, from 5% for Jacupiranga to 15% for Araxa. Flotation is carried out after a double desliming with, generally, a roughing operation followed by one or two scavenging operations, the froth being cleaned two or three times. The depression of carbonates and iron oxides is achieved at a pH of about 10 with causticized starch, and the flotation is carried out with fatty acids (tall oil). Concentrates of about 35% P_2O_5 with recovery ranging from 45% to 78% are obtained from different localities (Betz 1979). Lima (1993) carried out a comparative study of direct anionic flotation versus the reverse of the Jacupiranga phosphate, and demonstrated that double flotation with a reverse second step was not an adequate route. The superficial characteristics of the apatite and calcite of this deposit seem to indicate that the direct flotation process is the most adequate route (Lima 1993). At the same time, Leal Filho and Chares (1993) studied the beneficial role of starch in the separation of apatite from the Brazilian igneous low-grade phosphate/carbonate ores. They observed that cornstarch promotes the flotation of apatite, phlogopite, and dolomite; they observed no effect over calcite.

Finland

For the Finnish igneous phosphates (which contain about 10% apatite, 22% calcite and dolomite, 65% phlogopite, and 3% amphibole and other silicates), the flotation process is carried out using substituted N sarcosine (amphoteric compound). Flotation is performed at a basic pH (8 to 11). The flowsheet adopted is grinding to 38.5% –74 μm , one roughing flotation stage, and five cleaning flotation stages. Applying this flowsheet at the Siilinjärvi plant, a concentrate of 33.7% P_2O_5 with a recovery of 85.8% is obtained.

Mexico

Anionic rougher-cleaner flotation has been practiced in Mexico for many years. The flotation collector is a fatty acid emulsified with petroleum sulfonate and diesel oil.

Magnetic Separation

At the Phalaborwa Igneous Complex in South Africa, the pyroxenite zone is followed by the foskorite zone. This part of the ore body consists mainly of magnetite, serpentine, and apatite (Schmidt 1999). The P_2O_5 content in this zone varies from 6% to 11%. The magnetite must be removed using magnetic separation to upgrade the ore to commercial-grade rock. In the foskorite circuit, the crushed ore is conveyed to a 60-kt stockpile, reclaimed by three plough reclaimers, and conveyed to the milling plant. After copper flotation, Sala low-intensity magnets remove the magnetite after 750-mm and 100-mm Multotec cyclones remove

the slimes. Magnetic separation is also conducted on the PMC tailings before phosphate flotation.

At the Kapuskasing Phosphate Operations in Canada, magnetic separation is carried out on the final flotation product. The re-cleaner flotation concentrate is pumped to a reconditioned high-gradient magnetic separator (HGMS) purchased from the Iron Ore Company of Canada. The HGMS reduces the iron content from approximately 5% to less than 2%. HGMS product is pumped to a concentrate thickener.

At an Egyptian mine, the run-of-mine ore is delivered from the underground mines to a storage area where it is screened at 60 mm, the oversize of which is crushed in a rotary crusher. The crushed ore is screened again at 60 mm. The resultant oversize (+60 mm) is discarded because of its high impurities, and the fraction below 60 mm is delivered to the beneficiation plant for further treatment. In the beneficiation plant, the −60-mm fraction is scrubbed in a 3.6×10 -m drum scrubber to disintegrate the ore. The scrubbed product is then screened on 2-mm screen. The oversize fraction (+2.0 mm) is discarded because of its high dolomite content. The fraction below 2 mm is classified using a group of hydrocyclones to separate the clay fraction below 0.080 mm. The latter is discharged to the main thickener of the plant as slimes. The deslimed product (−2.0 + 0.080 mm) then goes through a second stage of washing in attrition scrubbers. A hydroseparator further classifies the product of the latter, at about 0.2 mm, into coarse and fine fractions. The coarse fraction (−2.0 + 0.2 mm) is filtrated and dried to ~1.5% moisture. This fraction represents the coarse concentrate. In the meantime, the fine fraction (−0.2 mm) from the hydroseparator is discharged to a group of hydrocyclones for further classification to separate the slimes below 0.080 mm. The underflow of the hydrocyclones (−0.2 + 0.080 mm) is then discharged to a high-intensity magnetic separator to separate the ankerite (ferrogenated dolomite) impurities as magnetic product. The nonmagnetic fraction (fine concentrate) is then filtered and dried. Both coarse and fine concentrates are blended to produce a final concentrate assaying ~30% P_2O_5 and 0.55% MgO.

Magnetic separation is also practiced in Togo and Mexico.

Calcination

Calcining is used to treat phosphate rock to achieve one or more of the following objectives:

- To remove carbonaceous materials, dolomite, or calcite
- To remove organic matters
- To improve reactivity of the rock
- To make low-grade, slow-release fertilizers

Calcination (at higher than 700°C) is widely used in Morocco to eliminate organic materials from the so-called “brown” or “black” phosphate rock.

In the last decade, calcination was studied and recommended to treat phosphate ores in Saudi Arabia, where water supply is limited and energy is inexpensive. In the study, a Saudi phosphate ore containing 40% to 50% carbonate and 16% to 25% P_2O_5 was treated by calcination at 850°C for about an hour, followed by quenching with 5% ammonium nitrate (NH_4NO_3), 5% ammonium chloride (NH_4Cl), or water. Under the best test conditions, a concentrate containing 38% P_2O_5 was obtained (Al-Fariss 1993).

Two low-grade Indian carbonaceous ores were successfully upgraded using a continuous-flow calcination process. Phosphate recoveries ranged from 63% to 84.6%, with concentrate grades of 31.3% to 38.5% P_2O_5 . The roasting temperature was 900°C (Good 1976).

Beneficiation of Sedimentary Carbonaceous Phosphates

Sedimentary carbonaceous phosphate ore is, by far, the most widely present in the world and constitutes more than two thirds of present-day reserves. Some deposits, though, are being beneficiated using calcination processes followed by elimination of CaO fines. Because of ever-increasing energy costs, more economical means are becoming increasingly attractive, including the froth flotation process. The largest difficulty, however, arises from the fact that the physicochemical properties of phosphatic minerals and carbonates are very similar (Waksmundzki, Neczaj-Bruzewica, and Planik 1971). In the last three decades, numerous studies have been carried out to separate carbonaceous gangue from sedimentary phosphate ores. These processes include direct flotation of phosphate with depression of the carbonate gangue (Awasthi et al. 1977) and reverse flotation of the carbonate gangue with depression of the phosphates (Smani, Cases, and Blazy 1975; Awasthi et al. 1977; El-Shall 1994).

China

China is quite successful in processing sedimentary carbonaceous phosphates using flotation technology, perhaps because the majority of their phosphate deposits (about 80%) belong to this category. The Chinese phosphate resources have three distinct characteristics: old geological age, high dolomite and other impurities, and being finely disseminated. Before beneficiation, fine grinding is usually required to liberate impurity minerals from phosphate. About 98% of the phosphate deposits occurred in Cambrian or Sinian formation at the age of more than 500 million years. Because of old geological age, the phosphate rocks are usually in massive and very hard structures.

The Jinping phosphate mine is located in Lianyungang of Jiangsu Province. The processing plant was put into operation in the late 1950s with the capacity of 1.2 Mtpy mining and beneficiation. At the early stage of production, the run-of-mine did not contain much MgO. A process with soda ash as pH modifier, water glass as the silica depressant, and crude tall oil as phosphate collector could produce very high quality phosphate concentrate. As the high-grade ore was depleted, the MgO impurity was gradually increasing, up to about 10%. A new process was therefore developed and implemented. The as-mined ore is subject to two-stage crushing to −50 mm, and then ground in a closed circuit of ball mills and spiral classifier to −0.3 mm (containing 40% −200 mesh) as flotation feed. The feed slurry in 42% to 45% solids is conditioned with Na_2CO_3 , L_{339} , and crude tall oil, and is transported to flotation operations consisting of one rougher, two scavengers, and three cleaners. The froth product as concentrate is gravity flowed to a thickener for first-stage dewatering. The underflow in 70% solids is further dewatered through drum filters, and the filter cake is then dried in a revolving tubular kiln to obtain dry phosphate concentrate.

The Dayukou, Hubei, phosphate ore contains 17% to 18% P_2O_5 and 4% to 5% MgO. Phosphate, dolomite, and silicate in the ore were intergrown in extremely fine particles. To achieve the desired degree of liberation phosphate from gangue minerals, the ore must be ground to a fineness of −0.1 mm (over 90% −200 mesh). For such fine particle sizes, it was once considered almost impossible to separate dolomite from phosphate by the flotation method. The Dayukou phosphate beneficiation plant was put into operation in 1996. The success of the “direct flotation” process relies on the “S” series depressants developed by Lianyungang Design and Research Institute (CLDRI) especially for effective depression of both carbonates and silicates. The “S” series depressants were derived from the by-product of petroleum industry. For beneficiating Dayukou

phosphate ore with the direct flotation process, CLDRI also developed an effective collector, PA-42, using a waste material from vegetable oil processing. PA-42 is very selective.

The flotation section of the process is in a closed circuit. The underflow of first cleaning flotation is subject to a scavenging operation, which is a key step for effective rejection of MgO impurity.

The Wengfu phosphate project, in Guizhou Province, is currently the largest integrated phosphate fertilizer complex in China, consisting of 2.5 Mtpy of beneficiation capacity, 800,000 tpy TSP, 800,000 tpy sulfuric acid, 300,000 t (P₂O₅ basis)/year phosphoric acid, and 12,000 tpy aluminum fluoride.

The run-of-mine ore containing about 30% P₂O₅ and 4% to 4.5% MgO is crushed to -15 mm. The crushed ore is then ground in an overflow ball mill. Hydrocyclones are used to control the milled product in the range of 60% to 68% -200 mesh for mineral liberation. The feed slurry of 40% solids is conditioned with H₂SO₄ as a pH modifier and PA-31 as dolomite collector, and is then subject to carbonate flotation to remove dolomite as froth product. The rougher sink is cleaned and refloated to further reject dolomite. After dolomite removal, the final sink product is dewatered using a high-capacity thickener to obtain a phosphate concentrate slurry of 70% solids.

The concentrate analyzing 36% P₂O₅ and 0.95% MgO is obtained at the overall P₂O₅ recovery of 95%. The removal rate of MgO impurity is over 80%. The minor element ratio value of the product is very low, only about 0.033.

Vernal, Utah (United States)

In Vernal, Utah, ore from the surge pile is conveyed to an 8.2-m diameter × 1.5-m semiautogenous grinding (SAG) mill, which has a 1,900-kW power capability; there it is ground at 76% solids with a 7% load of 10-cm-diameter balls (Allen 1993). The mill discharge is trommel-screened at 20 mm, with undersize pumped to vibrating screens, which return a +8-mm oversize to the SAG mill. The trommel oversize is ground at 73% solids to passing 20 mesh in a 4.1-diameter × 6.1-m ball mill, which has a power capacity of 1,500 kW. The ball mill discharge joins trommel undersize and is pumped to vibrating screens with the oversize returned to the ball mill and undersize carried to a large slurry storage tank.

This slurry is diluted from 50% to 15% solids with reclaimed water and deslimed in 66-cm-diameter hydrocyclones. The cyclone overflow at 7% solids flows by gravity to the tailings pond, and underflow at 50% solids feeds desliming hydrosizers. The hydrosizer overflow at about 7% solids flows by gravity to a scavenger dewatering circuit. The hydrosizer underflow flows by gravity to rougher conditioners, where at 70% solids the flotation reagents mix with the ore for about 8 min. Four reagents are added into the first conditioner of three in series: fatty acid, petroleum sulfonate, diesel fuel, and a frother. Conditioning is carried out at a natural pH of 7.5 to 7.9. The rougher flotation feed (240 tph) is floated at 25% solids with a retention time of about 6 min to produce a concentrate that proceeds to the cleaner cells where retention time is about 14 min with a feed at 35% solids. The cleaner concentrate has recently averaged 31.5% P₂O₅ and 0.6% MgO.

Rougher flotation tailings report to a scavenger dewatering cyclone sump together with cleaner tailings and hydrosizer overflow. The dewatering overflow reports to tailings and underflow at 72% solids flows to a scavenger section ball mill hydrocyclone grinding circuit. The grinding circuit hydrocyclone overflow reports to a circuit consisting of three-stage hydrocycloning in series, with the third-stage overflow used as dilution for the second-stage cyclone feed. The overflow from the first and second stage reports to tailings. The third-stage desliming underflow at 70% sol-

ids flows to the two scavenger conditioners in series, where the same four reagents used in rougher conditioning are added to the first conditioner and mixed for about 15 min at the natural pH of 7.5 to 7.9. The scavenger-rougher flotation at about 25% solids has a residence time of 12 min. Tailings at 9.5% P₂O₅ are recirculated to the desliming hydrocyclones before hydrosizing, and the scavenger-rougher concentrate reports to the scavenger-cleaners at 25% solids, where flotation proceeds for about 13 min more. After the addition of some sulfuric acid, the scavenger-cleaner concentrate, at 29.4% P₂O₅ and 1.1% MgO, passes through an acid-stripping hydrocyclone to remove fatty acid/diesel fuel and lower pH to depress phosphate in the carbonate flotation step. The hydrocyclone underflow at 70% solids is diluted to 55% solids and conditioned in two tanks in series for about 6 min, with additional petroleum sulfonate and frother. The carbonate flotation is done at 25% solids with a retention time of about 8 min. The concentrate (cell product) runs about 30.7% P₂O₅ and 0.75% MgO and is combined with primary cleaner concentrate as a concentrate product representing about 36% of crude ore feed weight. This combined concentrate is dewatered from 17% solids to 75% solids in the underflow and then ground in a 4.1-m-diameter × 6.1-m ball mill with 1,500 kW power, operated in closed circuit, with hydrosizers. The hydrosizer overflow at 20% solids reports to product thickeners to achieve a 60% solids underflow after addition of a small quantity of flocculant and is then pumped to mixed product storage tanks.

The CLDRI Process for Florida Dolomitic Pebbles

Under FIPR funding, IMC Phosphates conducted two major projects to develop an economically feasible process for high-dolomite phosphate pebbles in Florida. The Chinese CLDRI worked with IMC as the primary subcontractor for laboratory development and pilot-scale evaluation of flotation processes for dolomitic pebbles. As a result, the CLDRI process was developed. A typical flowsheet of the CLDRI process involves grinding, dolomite flotation, and silica flotation. It must be pointed out that, unlike most previous processes, the CLDRI process does not require the desliming step after grinding, thus reducing phosphate loss. Pilot-plant testing on two Florida samples achieved encouraging results similar to or better than those obtained in laboratory tests. An economic analysis was conducted based on the pilot testing results for a 272-tph (300-stph) battery limit plant. The estimated variable (production rate dependent) costs (including raw materials, electric power, reagents, consumables, severance tax, dam building, services, and contract maintenance) add up to \$13.80/t (\$12.52/st) of concentrate. Fixed costs (including labor, overhead, depreciation, supplies, taxes, and insurance) total an estimated \$3.42/t (\$3.10/st) of concentrate. Total operating costs, which are the sum of variable and fixed costs, are estimated at \$17.22/t (\$15.62/st) of concentrate. These numbers suggest that the CLDRI process is economically feasible under the current conditions. The battery limit plant includes silica flotation, which reduces the concentrate acid insolubles from 19% to 6%.

REGULATORY AND ENVIRONMENTAL CONSIDERATIONS

The environmental issues related to phosphate mining and processing, particularly in Florida, are summarized in the following sections.

Waste Clay Ponds

As described previously, the phosphate matrix (ore) must be deslimed before flotation. A typical Florida phosphate matrix is composed of roughly one third each of phosphate, clay, and sand, resulting in the generation of approximately 1 t of clay waste (phosphatic clay) for each ton of phosphate rock product. At the current

mining rate, the industry is generating nearly 100,000 t of waste clay each day, which is pumped to the settling areas as a dilute slurry. Assuming an average solids load of 3% in the slurry, more than 3 Mt/day of slurry need to be pumped to the settling ponds. Although impounding is the most economical method for disposing of waste clay, it has several major disadvantages. Clay settling ponds occupy about 40% of mined lands and generally have limited use after reclamation, causing adverse economic impacts. The waste clay ties up a large amount of water. Clay ponds also cause a significant loss of water through evaporation because of their large size (up to 800 acres each). The impacts of clay settling ponds on the hydrological system are not yet fully understood.

Process Water

All phosphate fertilizers in Florida are produced using “wet-process” phosphoric acid. The wet acid is produced by dissolving phosphate rock in sulfuric acid solution, which generates acidic water designated as process water. This process water plays four major roles in the operation of phosphoric acid plants: (1) supplying make-up water for phosphoric acid manufacture, (2) conveying the phosphogypsum to the stack, (3) removing the heat generated during phosphoric acid manufacture, and (4) scrubbing all the exhaust gases within the chemical complex to prevent the discharge of undesirable gases to the atmosphere. Through all these functions, the process water reaches an equilibrium content of all the materials found in both the phosphate rock and the sulfuric acid. Although the plants are net water users, rainfalls often make it necessary to treat and discharge surplus water. The surplus water is first treated by neutralization with lime to remove fluoride and phosphate, followed by aeration to remove ammonia, followed by the addition of sulfuric acid to bring the pH into the range from 6 to 7. This process is expensive, and even after treatment, the water does not meet the standards for surface discharge. The industry would benefit greatly from the discovery or development of a technology that would remove any or all of the soluble salts or that would raise the pH of the process water economically.

Phosphogypsum Stacks

Phosphogypsum is a by-product of phosphoric acid manufacture. For every 1 t of phosphoric acid produced, approximately 5 t of phosphogypsum are produced. About 1 billion t of phosphogypsum have accumulated in Florida, and 30 Mt are added to the inventory each year. Many efforts have been made to turn this waste into a major asset to the state. For example, research has demonstrated that significant economic benefits can accrue from using phosphogypsum in road construction and agriculture, without creating excessive risks.

The Hydrological Systems

As Florida keeps its pace toward becoming the third most populated state in the nation, water supply—both in terms of quantity and quality—is of strategic importance. Proper water flow is necessary both to supply human needs and to maintain the ecological health of the Peace River, its tributaries, and the Charlotte Harbor estuary, among others. These issues are also of universal significance. Limited research has been conducted to investigate mined lands as water treatment and storage systems, but this topic should be studied further.

Public Health Issues

Most potential hazards associated with the phosphate industry are found in the chemical plants, where major chemical emissions include sulfur dioxide, ammonia, sulfuric acid, and silicon tetraflu-

oride. Other potential emissions are radon gas and leachate from phosphogypsum stacks, along with fugitive dusts from product storage. Although no study has shown significant health risks for either the workers or the nearby residents, efforts to minimize emissions continue. For the mining and beneficiation sites, flotation reagents are biodegradable and are further attenuated by sandy soil before reaching the surficial aquifer, except in the case of fuel oil. Research to study the spatial migration and persistence of fuel oil in the environment is ongoing.

OUTLOOK AND FUTURE TRENDS

Onsite Processing of Phosphate Rock

As energy costs increase, it is becoming increasingly less attractive economically to ship phosphate rock globally. The recent trend toward increased deep processing of phosphate rock where it is mined will continue. As the trade data in Table 3 show, trade in processed phosphate increased by more than 50% from the 1980s to the 1990s. Another reason for this trend is the historically “unfair” pricing for phosphate rock. Whenever the phosphate fertilizer market improved, significant upswing occurred for DAP prices, although rock producers did not benefit because of their being improperly recognized as a cost center rather than a profit center. In the foreseeable future, more processed phosphates in the forms of high-grade fertilizer or phosphoric acid will be produced from Morocco, China, Jordan, Australia, and Tunisia.

Industry Consolidation

Consolidation in the United States probably peaked with the Cargill–IMC merger into Mosaic in late 2004. The same cannot be said about China. China has nearly 500 independent phosphate fertilizer enterprises (Wu 1998). The production capacity of the big and middle-size enterprises is only 35% of the total capacity. Many of the small-size single superphosphate and furnace calcium and magnesium phosphate enterprises have outdated technical equipment and urgently need to be adjusted or reconstructed because of poor product quality, high energy consumption, and poor waste disposal practices. Consolidation is already happening in China and will intensify in the next decade toward more privatization and internationalization, as shown by the Cargill DAP venture in Yunnan Province.

Privatization may also take place in other major phosphate-producing countries such as Morocco, Jordan, Russia, and Tunisia. Phosphate mining companies are nearly all operated by the governments in these countries.

Sustainable Mining

The mining industry as a whole has been challenged intensively in recent years by environmental groups and local governments that try to reduce or eliminate mining, in many cases through litigation. The Florida industry, for example, is facing a tough fight in obtaining new permits. Several county governments are pooling money to challenge IMC in the courts for permit extension or new permits.

Some of the challenges can be contributed to communication gaps between the industry and numerous stakeholders. Many other cases are legitimate concerns about the sustainability of the industry. Whether being forced or voluntary, the industry will have to direct more resources at developing projects that support sustainability.

Potash

Michel Prud'homme and Stanley T. Krukowski

INTRODUCTION

Potash is a generic term that includes potassium chloride (KCl), potassium magnesium sulfate ($K_2Mg(SO_4)_2$), potassium sulfate (K_2SO_4), potassium nitrate (KNO_3), and mixtures of sodium nitrate and potassium nitrate. The ceramics industry uses potash to refer to potassium oxide (K_2O). Potash in the form of potassium carbonate (K_2CO_3) was the first industrial mineral produced in the United States. The first patent issued in the United States was for an apparatus and process developed in 1790 for potash production (Paynter 1990). Before the 1860s, potash was sold mainly as an impure form of K_2CO_3 , produced by burning hardwood trees and leaching the potassium salts from the ashes. Primary early uses of potash included glassmaking, soapmaking, dyeing fabrics, baking, and using saltpeter for gunpowder.

In 1859, a purification process to remove sodium and magnesium chlorides was developed for carnallite ($KCl \cdot MgCl_2 \cdot 6H_2O$) found at Stassfurt, Germany; and mined potash became available. With the appearance of mined potash and the earlier (1840) discovery in Germany by Justus von Liebig that potash was a nutrient for crops, potash started to be used for high-value crops such as cotton and vegetables. The German potash companies quickly developed a manufacturing process for producing potassium sulfate for tobacco fertilization. German potash supplied nearly all U.S. consumption until it was embargoed during World War I. The United States became self-sufficient in potash when potash deposits were discovered in New Mexico in 1931. In 1962, the United States began importing potash from Canada, and 2 years later, domestic apparent consumption began to exceed domestic production.

Along with nitrogen and phosphorus, potassium is one of the three essential plant nutrients (the “K” of “NPK” terminology). As a result, 95% of potash production is used as plant fertilizer. For all plants, inadequate potassium diminishes growth and causes increased disease, stalk and stem breakage, and susceptibility to other stress conditions. Plants take up large quantities of potassium from the soil, and potash fertilization replaces this loss so that each new crop can grow with the same vigor and productivity as the previous year's crop. Potassium depletion of the soil from growing repeated cotton and tobacco crops is well known in the history of agriculture in the southern United States. For example, George Washington experimented with a lternative crops that could be grown on soil depleted by repeated tobacco harvests.

The chemical industry consumes most of the remaining 5% of potash production. Potassium hydroxide (KOH) is used to produce soaps and detergents, glass and ceramic products, dyes, explosives, alkaline batteries, and medicines. Other chemical applications are oil-field drilling mud, aluminum recycling, and electroplating. Minor uses for potassium chloride include water softener regeneration, sidewalk deicing, and salt (NaCl) substitution for human consumption. Potash is used in the food industry as potassium phosphate (monobasic, KH_2PO_4 , or dibasic, K_2HPO_4) and in production of glass products as potassium carbonate or nitrate.

GEOLOGY

Potassium is the seventh most abundant element in the Earth's crust and the sixth most abundant element in seawater. It is found in silicate minerals of igneous, metamorphic, and sedimentary rocks, and is a major constituent of many surface and subsurface brines. Most of world potash resources are found in subsurface, bedded salt deposits that yield high-grade, large tonnage ore bodies amenable to low-cost mining and beneficiation. Some potash production is from evaporation of naturally occurring brines. Because of the relatively high solubility of potassium minerals, potash from salt deposits is ideal for use as fertilizer.

Sylvite (KCl), carnallite ($KCl \cdot MgCl_2 \cdot 6H_2O$), kainite ($(4KCl \cdot MgSO_4) \cdot 3H_2O$), and langbeinite ($K_2(SO_4) \cdot 2MgSO_4$) are some of the more important potassium minerals (Table 1). Sylvite, a mixture of KCl and NaCl, is the highest-grade potash ore. Carnallite is considered a potash ore when magnesium chloride ($MgCl_2$) is removed during beneficiation, but it is considered a contaminant when mining for sylvite. Potassium sulfate and potassium nitrate typically are manufactured products. In 2004, potassium sulfate was produced from mined minerals through conversion processes in Germany and in the United States (e.g., potassium magnesium sulfate in Carlsbad, New Mexico), and from brines in Chile, China, and the United States (e.g., Great Salt Lake in Utah). Natural deposits of potassium nitrate occur only in small amounts in Chile.

Most potash-bearing bedded salt deposits are believed to have originated from evaporation of seawater or mixtures of seawater and other brines in restricted marine basins (Schmalz 1969). Ochsnius first described the reflux depositional model for evaporite deposition in the literature in 1888. A shallow bar, or sill, across

Table 1. Some minerals, ores, and products of potash deposits

Name	Chemical Formula	K ₂ O, equivalent wt %	Remarks
Minerals			
Chlorides			
Sylvite	KCl	63.17	Principal ore mineral
Carnallite	KCl•MgCl ₂ •6H ₂ O	16.95	Ore mineral and contaminant
Kainite	4(KCl•MgSO ₄)•H ₂ O	19.26	Important ore mineral
Bischofite	2MgCl ₂ •12H ₂ O	0	Accessory contaminant
Halite	NaCl	0	Principal ore contaminant
Sulfates			
Polyhalite	K ₂ Ca ₂ Mg(SO ₄) ₄ •2H ₂ O	15.62	Ore contaminant
Langbeinite	K ₂ SO ₄ •2MgSO ₄	22.69	Important ore mineral
Leonite	K ₂ SO ₄ •MgSO ₄ •4H ₂ O	25.68	Ore contaminant
Schoenite (picromerite)	K ₂ SO ₄ •MgSO ₄ •6H ₂ O	23.39	Accessory
Glaserite (aphthalite)	3K ₂ SO ₄ •Na ₂ SO ₄	42.51	Accessory
Syngenite	K ₂ SO ₄ •CaSO ₄ •H ₂ O	28.68	Accessory
Bloedite	Na ₂ SO ₄ •MgSO ₄ •4H ₂ O	0	Accessory
Loewite	6Na ₂ SO ₄ •7MgSO ₄ •15H ₂ O	0	Accessory
Vanthoffite	3Na ₂ SO ₄ •MgSO ₄	0	Accessory
Kieserite	MgSO ₄ •H ₂ O	0	Common ore contaminant
Hexahydrate	MgSO ₄ •6H ₂ O	0	Accessory
Epsomite	MgSO ₄ •7H ₂ O	0	Accessory
Anhydrite	CaSO ₄	0	Common ore contaminant
Ores			
Sylvinites	KCl + NaCl	20–35	Canada, United States, CIS, * Brazil, Congo, Thailand
Hartsalz	KCl + NaCl + CaSO ₄ + (MgSO ₄ •H ₂ O)	10–20	Germany
Carnallite	KCl•MgCl ₂ •6H ₂ O + NaCl	10–16	Germany, Spain, Thailand
Langbeinite	K ₂ SO ₄ •2MgSO ₄ + NaCl	7–12	United States, CIS
Mischsalz	Hartsalz + carnallite	8–20	Germany
Kainite	4KCl•4MgSO ₄ •11H ₂ O + NaCl	13–18	Italy, Ethiopia, CIS
Products			
Potassium chloride	KCl	63.17	Principal potassium product
Potassium sulfate	K ₂ SO ₄	54.05	Artificial product
Potassium-magnesium-sulfate (langbeinite)	K ₂ SO ₄ •2MgSO ₄	22.69	Natural product (New Mexico)
Manure salts	KCl + NaCl	40–60	CIS and Germany
Other Sources			
Alunite	K ₂ Al ₆ (SO ₄) ₄ (OH) ₁₂	11.4	
Niter	KNO ₃ + NaNO ₃ + Na ₂ SO ₄ + NaCl	0.6–1.9	Chile

Figure 1. The reflux model of evaporite deposition. Evaporation of seawater entering the basin over a restricting sill increases in salinity at the distal end of the basin. Contours represent density of the brine. The least-soluble minerals precipitate near the inlet, and halite precipitation occurs furthest from the inlet.

the mouth of a basin restricts the inflow of seawater, which upon further evaporation becomes a salt-precipitating brine (Figure 1). At the distal end, the brine increases in density and salinity, sinks to the bottom, and creates a reflux current of higher-density brine back toward the ocean. The sill inhibits the outflow of concentrated brine back to the ocean. Least-soluble salts precipitate nearer the sill, and the most-soluble components precipitate out of solution in the deeper parts of the basin. The result is a tabular-shaped deposit with lateral facies changes resulting from salinity gradients in the brine (Figure 2A). The asymmetrical facies distribution of the Paradox Formation (Middle Pennsylvanian) in Utah (Hite 1970), the Prairie Formation (Middle Devonian) in Saskatchewan (Holter 1972), and the Salado Formation (Upper

Figure 2. (A) Asymmetrical facies distribution of evaporite deposit formed by reflux model deposition; (B) Bull's-eye pattern of evaporite facies resulting from deposition in a basin drawdown model

Permian) in New Mexico (Lowenstein 1988) might be explained by such a model. Other deposits such as the Salina Formation (Upper Silurian) in Michigan (Matthews and Egleson 1974) show a facies distribution described as a bull's-eye pattern. Although some small sub-basins of high-grade sylvinite are found near the margins, the potash generally is located in a central part of the basin surrounded by successively less-soluble facies (Figure 2B). The sparse data available on the Miocene Mediterranean evaporite (Hsu 1972) also suggest a bull's-eye facies distribution.

Sedimentary features in marginal carbonates of some evaporite basins suggest subaerial exposure (Cercone 1988; Peterson and Hite 1969). According to Hsu (1972), subaerial exposure was the result of a basin undergoing evaporative drawdown and was responsible for deposits such as the Mediterranean Evaporite of Miocene Age, the Permian Upper Zechstein in Europe, and the Silurian Salina evaporite deposit in Michigan. Maiklem (1971) suggests the same mechanism for the Devonian Prairie Formation in Canada. Fluctuations in water depth in any ancient evaporite basin could be related to sea level changes, groundwater inflow, precipitation, and meteoric runoff, making it possible for evaporite minerals to have been deposited in either deep or shallow water and to have experienced subaerial exposure before burial.

Seawater evaporation results in precipitation of carbonate minerals first, followed by calcium sulfates, halite, magnesium sulfates, and then magnesium and potassium chlorides. The ratio of sodium

to potassium in seawater is 27:1, and, in general, minable potash beds are associated with thicker halite deposits. The potash ore zone often is located near the tops of halite beds in relatively thin layers because potash precipitates from higher-salinity brines near the end of the evaporation sequence. Carnallite rather than sylvinite is precipitated from seawater after the magnesium sulfates because of the high concentration of magnesium in seawater (Figure 3).

Evaporites of marine origin that lack magnesium sulfate and magnesium chloride minerals are the result of postdepositional dissolution processes. Carnallite may have been altered to sylvinite by reaction with magnesium-poor brines (Boorchert and Muir 1964; Garrett 1970; Braitsch 1971) or meteoric water (Hite 1982). In sylvinite deposits in Thailand, Republic of the Congo, and the Elk Point Basin of Canada, there is evidence that point-source ingress of meteoric water or seawater locally destroyed precursor carnallite, leaving sylvinite or only barren halite behind. In some instances this diagenetic process began shortly after the deposition of carnallite (e.g., the Thailand deposits), and the process may be occurring even today (Hite 1982). Recognition that nonmarine evaporite deposits are not necessarily restricted to small, terrestrial saline lake basins, however, led some workers to reassess the importance of mixing brines from seawater with other brines or with meteoric water (Hardie 1984; Williams-Stroud 1994). Some modern evaporites such as the Basque Lakes in British Columbia, Canada (Jones 1966) and those in the Qaidam Basin of Western

China (Lowenstein, Spencer, and Pengxi 1989), which are clearly nonmarine in origin, precipitate a suite of minerals very similar to those precipitated from seawater.

Theoretical and experimental salt assemblages calculated by D'Ans (1933) bore close resemblance to naturally occurring assemblages. The presence or absence of some accessory minerals in naturally occurring evaporite deposits was explained by changing

**Figure 4. Computer simulation of evaporation of altered seawater where the ratio of magnesium to calcium is approximately 1:1 instead of the seawater ratio of 5:1**

temperatures in precipitating brines, mixing brines of different compositions, and reacting brines with salts precipitated previously. Table 2 gives the theoretical assemblage of primary precipitates from seawater at 25°C by Braitsch (1971). Harvie et al. (1980) show a slightly different mineral sequence (Table 3) from that calculated by Braitsch. The former predicts the occurrence of polyhalite and glauberite (CaSO_4 , Na_2SO_4), which occur in many evaporite deposits believed to be of marine or igin, although in many of these deposits polyhalite appears to be secondary after anhydrite or gypsum. For deposits such as the Stassfurt horizon of the Permian Zechstein potash in Germany, the sequence of Harvie et al. (1980) suggests that the natural mineral assemblage could be primary and does not require postdepositional alteration (Table 3). The initial brine composition is critical to the sequence of minerals that precipitate upon evaporation, but the mixing of waters during evaporation also can have a profound effect on the sequence of precipitation. Figure 4 shows that it is possible to produce widely varying mineral suites by altering relative amounts of only one or two of the initial aqueous species.

Petrographic and textural relationships as well as chemical analyses of fluid inclusions of associated halites in potash evaporites suggest that sylvite occurred in many instances as a primary mineral (Wardlaw 1972; Lowenstein and Spencer 1990; Williams-Stroud 1994). The enrichment of seawater with calcium results in early depletion of sulfate by gypsum/anhydrite precipitation and prevents the deposition of magnesium sulfates. If there exists some mechanism for magnesium removal, then carnallite may not precipitate as

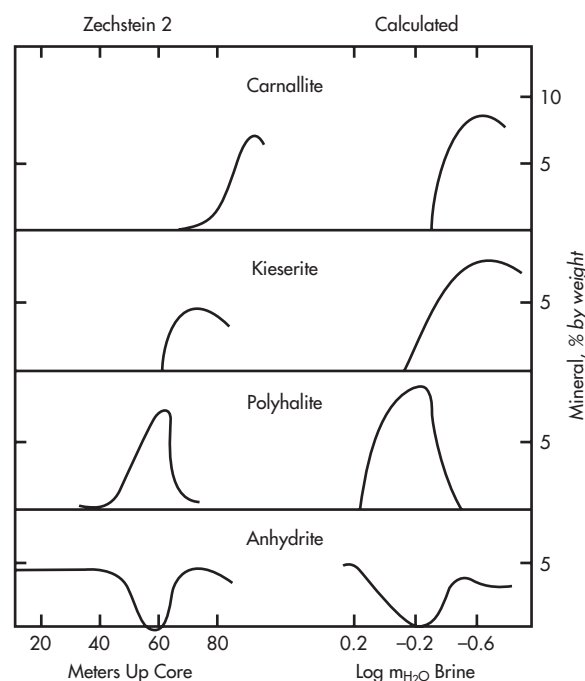

well, and sylvite will be the primary potash mineral deposited. Mechanisms for calcium enrichment or magnesium depletion include dolomitization of associated limestones or of a limestone precursor (Shearman 1966; Hite 1983), interactions with hydrothermal waters (Hardie 1990), and clay mineral cation exchange (Hite 1983). Sulfate depletion, which also may lead to nondeposition of magnesium sulfates, can occur through brine mixing (Raup 1970). When additional calcium enters into the system with other brines, sulfate may be consumed by precipitating gypsum and anhydrite before reaching saturation with respect to magnesium sulfate minerals.

Potash-bearing evaporites can be divided into two different types: magnesium sulfate-rich deposits (containing the minerals polyhalite, hexahydrate, kieserite, and epsomite) and magnesium sulfate-poor deposits (Hardie 1990). In the former, the primary potash mineral is carnallite, whereas the latter is characterized by sylvite and carnallite. The magnesium sulfate-rich evaporites (e.g., the Stassfurt horizon of the Permian Zechstein 2) exhibit the same mineralogy resulting from evaporation of modern seawater (Figure 5). The magnesium sulfate-poor potash deposits probably precipitated from brines high in calcium; these deposits constitute 60% or more of known potash basins (Hardie 1991). These two types of potash deposits display a distinctive temporal relationship (magnesium sulfate-rich types occurring only in the Permian, Miocene, and Quaternary; Figure 6), suggesting that changes in seawater composition occurred throughout Phanerozoic time or that many potash evaporite deposits did not precipitate from seawater, but were the result of the evaporation of nonmarine or mixed marine–nonmarine waters (Hardie 1991). Figure 7 shows the distribution of potash deposits that contain little or no associated magnesium sulfate salts. Many of the basins are smaller than the magnesium sulfate-rich evaporite basins, and some show an elongated shape, suggesting the formation in a graben or rift valley setting.

EXPLORATION

Evaporite deposits that are found in cratonic basins usually are associated with biogenic deposits such as shell carbonates and fringing reefs and with clastic redbed deposits. Some evaporite deposits are found at continental margins that were sites of tectonic extension during the Mesozoic and Cenozoic eras. The high solubility of evaporite minerals precludes the formation of salt outcrops in most parts of the world, and their occurrence generally is limited to the subsurface. The proximity of evaporite deposits can be inferred from saline waters in springs and wells, solution breccias, or thick outcrops of gypsum or anhydrite. Domal or collapse structures at the surface may indicate salt domes, or piercement structures, such as those found under and around the Gulf of Mexico (Halbouty 1967), under the North Sea, and in the Zechstein Basin (Trusheim 1960; Brunstrom and Walmsley 1969). Domes or anticlines that show on outcrop several periods of upward growth during a broad range of geologic time generally can be expected to have a central core of evaporites. The distribution and shape of subsurface salt structures also can be determined by geophysical techniques such as gravity and seismic methods (Sawatzky, Agarwal, and Wilson 1960).

Salt domes probably originated from the effect of gravity on layered rock where a lower-density material (e.g., salt) is overlain by higher-density material (e.g., sandstones, compacted shales, or carbonates). Compared to other geologic materials, the shear strength of halite and potash salts is very low, and the low compressibility maintains that low density even under deep burial conditions; low shear strength isabetted further by high temperatures associated with deep burial. Over geologic time, salt squeezes

Figure 6. Distribution of magnesium sulfate-rich evaporite deposits which occur only in the Permian, Miocene, and Quaternary

Figure 7. Distribution of magnesium sulfate-poor evaporites. Occurrences are throughout geologic time and not restricted to any particular geologic period.

Figure 8. Bromine profile from halite in the Zechstein 2 showing regular increase in the amount of bromine that substitutes for chlorine in the halite crystal lattice

upward because of the density differential with overburden and irrespective of the presence of lateral tectonic compression. Salt flow, therefore, can be modeled as a viscous fluid (Ramberg 1981). Points of instability (i.e., intersections of fault systems or differential loading) are sites for nucleation of salt pillows, or salt hills in the subsurface. As the salt masses continue to rise, anticlines formed in the overlying layers may be pierced by this upward-moving salt, producing mushroom-shaped salt diapirs, which, in extreme cases, may detach completely from the rest of the salt deposit (Jackson and Talbot 1986). In the arid climate of northern Iran, salt diapirs pierced through the surface and flow downhill as salt glaciers. The structure of the original depositional layering in the salt inside of a diapir is highly deformed and chaotic (Talbot and Jackson 1987), and may not be suitable for conventional potash mining techniques.

Most potash deposits were discovered while drilling for petroleum. Evaluation of oil and gas exploration geophysical logs (such as gamma-ray, neutron, sonic, caliper, density, and resistance logs) is useful in interpreting evaporite lithology, stratigraphy, and mineralogy (Alger and Crain 1968). The gamma-ray log detects the gamma radiation from the natural potassium isotope K^{40} and is particularly useful as a continuous measure of the potassium content of the salt section (Adams and Hite 1983). Bromine content of salt layers has been used to evaluate potash potential and is useful as an indication of the stage of evaporation, especially in waters that were predominantly marine in origin. Bromine will substitute for chlorine in halite as the brine becomes more concentrated; that is, the bromine content of the brine increases. Because potash precipitation occurs in highly concentrated brines, the halite in and near potash beds should contain more bromide. A bromine concentration profile from seawater salt should show regularly increasing bromine

content toward the top of the halite bed (Figure 8), whereas salt precipitated from mixtures of sea water and other waters or brines, or a salt that underwent extensive postdepositional recrystallization by groundwater, may show either an irregular profile or no increase in bromine. In northeastern Thailand, economic potash deposits were discovered using bromine geochemistry (Hite and Japakasetr 1979).

Table 4 lists some general guidelines for evaluating the features of an evaporite deposit, and these may determine the success of a mining operation. The initial appraisal is based on drill cores spaced on 400–1600 m centers, depending on the depth and complexity of the deposit. Salt cores are logged, paying attention to all mappable stratigraphic, lithologic, and mineralogical features, and the potash zones are sampled as individual geological units for chemical analysis. It is generally sufficient to analyze for K^+ , Na^+ , Ca^{2+} , Mg^{2+} , Cl^- , SO_4^{2-} , and H_2O . The chemical analyses and the megascopic mineralogy estimated from hand specimens and thin sections are used with stratigraphic data to develop a geologic model. Factors listed in Table 4 help determine the potential for a minable deposit or the need for additional drilling or metallurgical tests.

WORLD POTASH OCCURRENCE AND RESOURCES

The U.S. Geological Survey (USGS) estimates reserves of potash that are recoverable with existing technology from known deposits at approximately 8.3 Gt K_2O equivalents. Canada and Russia have approximately 53% and 21% of the world's total reserves, respectively. The United States has only about 1% of the world's potash reserves. The resource data compiled in Table 5 are based on USGS published information. For the most part, the reserves may best be referred to as probable ore, or ore whose occurrence is reasonably assured but not absolutely certain. There is some question, for example, as to the reliability of the reserves reported for the Commonwealth of Independent States (CIS, the former U.S.S.R.), as well as that portion of Canadian solution mining reserves that are actually recoverable.

North America

Canada

Canada has most of the high-grade sylvinite ore reserves in the world. Reserves recoverable by underground mining are estimated to be 4.4 Gt (Searls 2005), based on an ore grade of 24% to 32% K_2O and a maximum minable depth of 1,100 m. The zones may be as thick as 10 m, but grade varies from approximately 3% K_2O at the top and bottom to an average 27% in the center of the zones. In 2004, potash production capacity in Canada was estimated at close to 12.3 Mt K_2O , accounting for a 35% share of global capacity.

New Brunswick. One mine produces potash from the Windsor Group of Mississippian age in New Brunswick. High-grade ore (averaging between 21% and 25% K_2O) discovered in 1970 occurs in zones located 300 to 1,000 m below the surface (Miller 1982). Windsor Group evaporites are mostly sylvinite with local minor occurrences of carnallite. Evaporites are located in a fault-bounded synclinalorium and are structurally more complex than the Prairie Formation. In some places, evaporites are diapiric in character. One underground mine was flooded in 1997. Between 1998 and 2005 its processing facilities were used for further beneficiation of potash products into higher value granular grades (the plant was permanently closed in 2005).

Saskatchewan. Ten mines currently produce potash from the Middle Devonian Prairie Formation of the Elk Point Basin in Saskatchewan (Figure 9). Three potash horizons occur in the upper part of the evaporite sequence: Esterhazy, Belle Plaine, and

Table 4. Guides to the evaluation of potash deposits

Factor to be Considered	Potential Problem	Observation to Be Made
Structure of ore horizon	Faulting, folding, or flowage of ore horizon complicating or precluding room-and-pillar mining method	(A) Correlation of stratigraphy between drill holes; (B) examination of core for evidence of deformation and recrystallization
Stratigraphy	Incorrect correlation of ore horizons; salt thickness; above ore insufficient to protect deposit from water; slabbing, and ore dilution from clay beds above ore horizon	Detailed core logging and correlation of beds between drill holes
Ore depth	Low mine extraction or excessive development and mining costs	Mining method and size of mine openings designed on basis of rock mechanics and geology
Ore thickness	Local systematic or random thinning of ore zone	(A) Isopach maps of stratigraphic units and mineralization in ore zone; (B) inspection of core for evidence of metasomatism and potash leaching, i.e., recrystallized halite, clay in intergranular clots, and horizontal mineral zoning
Ore mineralogy	Assemblages incompatible with proposed mill circuit; certain assemblages reduce stability of mine openings; high insoluble content requires extra desliming capacity	Determinative mineralogy of core
Ore grade	Grade may be too low or erratic to maintain acceptable mill feed; recoverable K ₂ O may be significantly less than total K ₂ O	Correlation and interpretation of drill hole data; comparison of chemical analyses with determinative mineralogy
Ore continuity	Erratic barren or thin areas in ore zone	Correlation of stratigraphic units and mineralization in ore zones; inspection of core for evidence of recrystallization and horizontal mineral zoning
Ore crystallinity	Inclusion of contaminants within potash minerals; fine-grained assemblages requiring finer grind	Correlation of microscopic examination of ore samples with chemical analyses of mineral separates
Ore reserves	Insufficient reserves or excessive mining and milling costs	Accurate geological description of deposit for mining and metallurgical studies

Adapted from Adams and Hite 1983.

Patience Lake members. Potash zones are 20- to 25-m thick, and are composed primarily of halite, sylvite, and carnallite (Holter 1972). Distinct layers, or finely disseminated bands, form in the potash salt and are composed of varying amounts of insolubles consisting of anhydrite and gypsum, carbonates, quartz, hematite, and clays. The entire evaporite sequence dips gently to the south at 1 to 8 m/km, with potash horizons occurring from 600 to 2,500 m below the surface. Lateral continuity and only a gentle warping of the beds permit the use of continuous mining machinery in a room-and-pillar method that minimizes rock instability and ventilation problems.

United States

In the United States, three companies operated seven mines from near-surface brines, lake brines, and under ground deposits at the beginning of 2005.

Arizona. In east-central Arizona, the Supai Formation of Pennsylvanian and Early Permian age includes thick halite deposits that also host potash. Several companies extensively explored this area, known as the Supai Salt Basin, for potash from 1963 through 1966. Drilling outlined a northeast-trending sylvinite deposit underlying about 800 km² (Peirce 1969). The deposit proved highly discontinuous with high clay content. Depths to the deposit range from 200 to 600 m, and the deposit apparently is relatively undeformed.

California. Potash production in California was by mechanical evaporation of subsurface brines. This mining operation is currently not operating.

Michigan. The Salina Formation of Late Silurian age hosts a large potash resource. These resources consist of a sylvinite deposit in the A-1 Salt that underlies about 33,800 km² in the Michigan Basin (Matthews and Egleson 1974). The zone of mineralization is more than 30 m thick in the central part of the basin. The vertical concentration of sylvinite is somewhat erratic in this thick deposit, but some intervals show K₂O values up to 40%. Depths to the deposit in the basin center are as much as 2,550 m, and although these depths decrease toward the basin margins, the deposit can only

Table 5. World potash reserves for 2004, kt K₂O

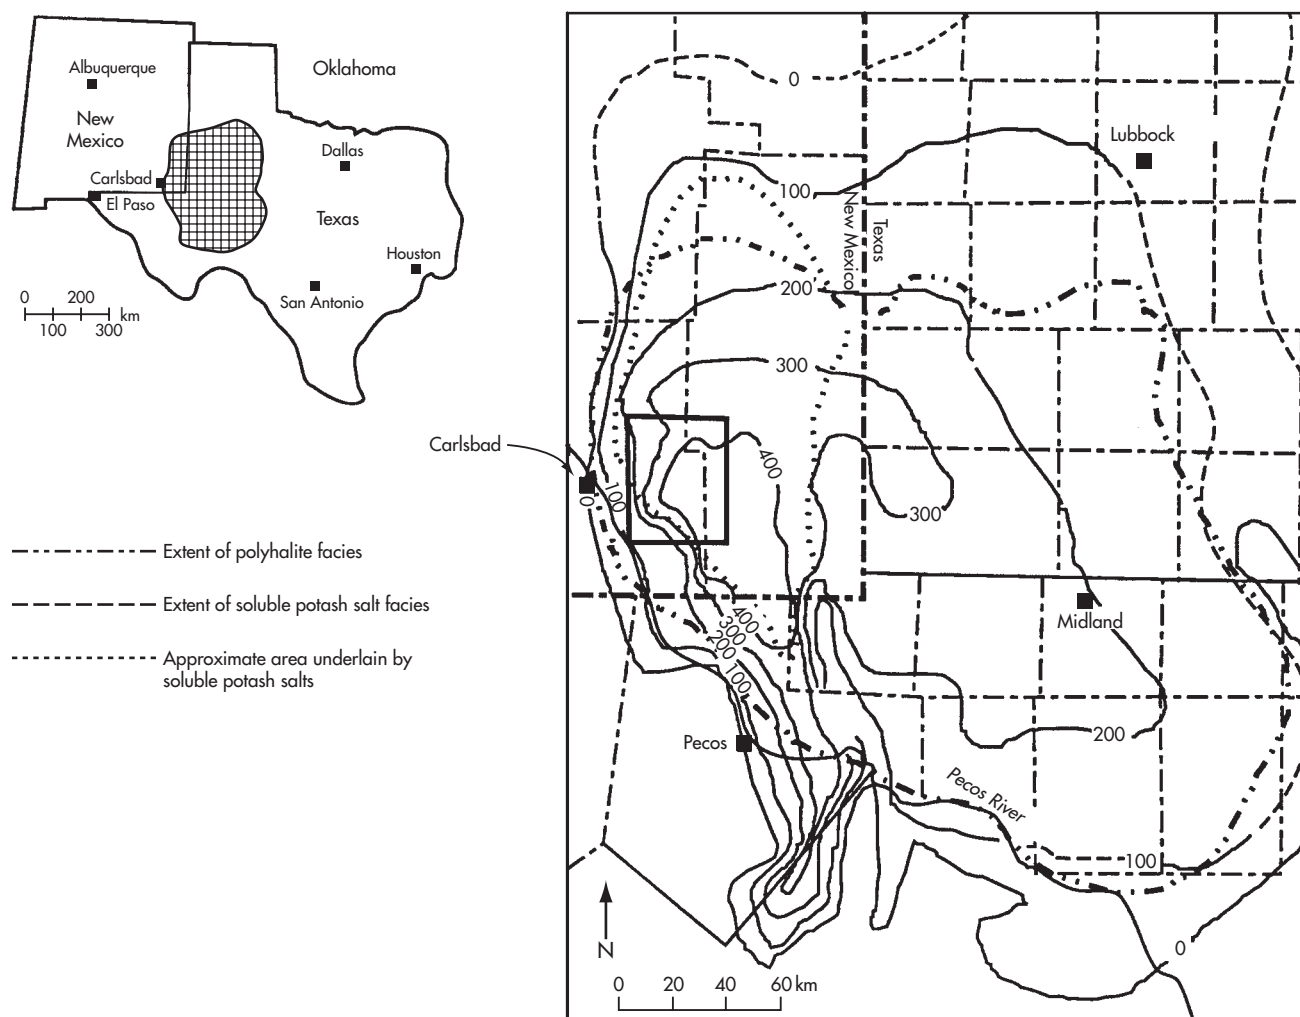

Country	Reserves	Country	Reserves
Belarus	750,000	Jordan	40,000
Brazil	300,000	Russia	1,800,000
Canada	4,400,000	Spain	20,000
Chile	10,000	Ukraine	25,000
China	8,000	United Kingdom	22,000
Germany	710,000	United States	90,000
Israel	40,000	Other countries	50,000

be mined by solution mining. Currently, the Mosaic Company (mine formerly owned by IMC Global Inc.) is using deep-well solution mining and mechanical evaporation for crystallization on muriate of potash (MOP) and by-product sodium chloride (Searls 2005).

New Mexico. Since 1931, most potash production in this state has come from the Carlsbad mining district in the Permian Delaware Basin of southeast New Mexico (Figure 10). In this district, the Salado Formation contains sylvinite, langbeinitite, and lesser amounts of sulfate minerals in 12 potash horizons that occur over approximately 5,000 km² (Jones 1972; Lowenstein 1988). Two companies were operating three New Mexico mines at the beginning of 2005: The Mosaic Company mine, formerly owned by IMC USA Inc., and the two Intrepid Mining LLC mines (formerly owned by Mississippi Potash Inc.). These mines extract potash ore from 5 of the 10 horizons (Searls 1985). The potash ore is confined to a relatively small interval of the Salado called the McNutt Zone, in which local barren patches of almost pure halite (called salt horses) complicate mining operations. Barker and Austin (1999) give an overview of the Carlsbad potash district.

Texas. The Palangana salt dome in southeastern Texas is the only salt dome in the Gulf Coast region that hosts a significant con-

centration of potash. The Palangana, which consists of sylvinite, was explored with 25 drill holes in the early 1960s (Hofrichter 1968). The internal structure of this salt diapir is very complex and caused the abandonment of the project.

Utah. The Middle Pennsylvanian Paradox Formation has large reserves of potash in the Paradox Basin of southeastern Utah and southwestern Colorado. These deposits are found in a thick sequence of evaporite cycles. Thirty-one cycles have been identified in this sequence and 18 are known to contain potash, although only 11 cycles contain potentially valuable deposits (Hite 1964). Potash deposits are found at depths suitable for conventional shaft mining only along a series of northwest-trending salt anticlines. In 1964, Texas Gulf Company sank a shaft on the Cane Creek anticline to a depth of about 850 m to mine a high-grade sylvinite deposit that occurs in the upper part of the evaporite sequence. After about 4 years, the company ceased mining by room-and-pillar methods and converted the underground openings to a solution mine.

Potash also is produced in Utah by solar evaporation of the brines of the north arm of the Great Salt Lake, and from shallow brines in the Great Salt Lake Desert at Wendover. At the beginning of 2005, two companies operated three Utah mines: Compass Mineral

operates one mine in Ogden and Intrepid Mining LLC operates two mines (formerly owned by Reilly-Wendover and Moab Salt).

South America

The South American continent has only a few potash evaporite deposits and, so far, no extensive, high-grade, continental craton-type evaporite such as that found in North America and Europe has been discovered.

Argentina

Potash reserves occur in the Argentinean Andes provinces of Neuquén and Mendoza in evaporites of Middle Cretaceous age. These reserves are nearly 1,000 m deep. Very high formation temperatures ($>50^{\circ}\text{C}$) may preclude underground mining, so solution mining methods were investigated. The ore is sylvinitic, which is divided into two zones. The upper zone averages about 3 m thick and the lower is about 11 m thick. The grade of the potash ore averages between 20% and 25% K_2O . Development of these deposits was tentatively pursued in the late 1990s. In 2004, Potasio Rio Colorado S.A., a subsidiary of Rio Tinto's Industrial Minerals Group, carried out a series of feasibility, marketing, and technical studies to develop a large solution mine in the Neuquén Basin. Also in 2004, Companhia Vale do Rio Doce SA of Brazil acquired the exploration license for a potash deposit in Neuquén to evaluate potash reserves and study the feasibility of solution mining.

Brazil

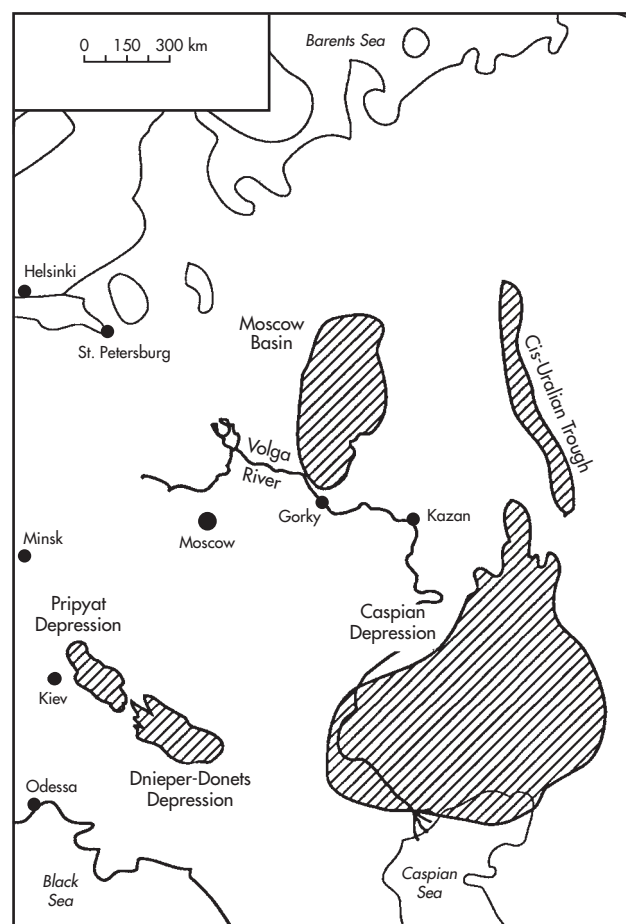

The large Amazonas Basin of Brazil contains sylvite-bearing evaporite deposits of Permian age (Szatmari, Carvalho, and Simões 1979). Two potential deposits near Manaus in the Amazon Basin are about 1,000 m deep with an average thickness of 2.7 m and average 16.5% K_2O .

A minor proven potash reserve in South America occurs in the Ibura Member of the Muribeca Formation of Middle Cretaceous age in the state of Sergipe. The deposits probably formed as a rift valley evaporite sequence that resulted from alteration of seawater brines by the addition of calcium-rich hydrothermal fluids during the separation of the African and South American plates in Jurassic to Cretaceous times (Wardlaw 1972). The mineralogy of the deposit includes halite, carnallite, sylvite, and tachyhydrite ($\text{CaCl}_2 \cdot 2\text{MgCl}_2 \cdot 12\text{H}_2\text{O}$). The tachyhydrite is very thick (up to 90 m) and nearly pure; it occurs in a bedded sequence displaying primary depositional growth fabrics of carnallite crystals in halite, but containing no bischofite and no magnesium sulfate minerals.

In 2004, production of potash came from only one underground operation mining the Ibura Member. The ore deposit is a complex structure with rapid and frequent lateral variation of sylvite and a thick underlying deposit of metastable tachyhydrite. The sylvinitic deposit is divided into two seams by a thin halite layer, which sometimes is missing. Because the ore directly overlies tachyhydrite, 3 m of sylvinitic must be left in the floor to prevent floor heave. Extreme variations in ore grade required the mining of large tonnages of barren salt.

Chile

Significant reserves occur in several salars surrounding the area where the borders of Chile, Bolivia, and Argentina meet. Potash production from the Salar de Atacama in Chile was expanded from about 50 ktpy KCl in the early 1990s to more than 800 kt KCl in 2004. Sylvinitic is recovered as a by-product of lithium production, mainly from the Sociedad Química y Minera de Chile (SQM). The bulk of potash production is used in manufacturing high-grade potassium nitrate. Potassium sulfate also is extracted as an associated

Figure 11. Distribution of Permian potash-bearing salt deposits in the East European Basin

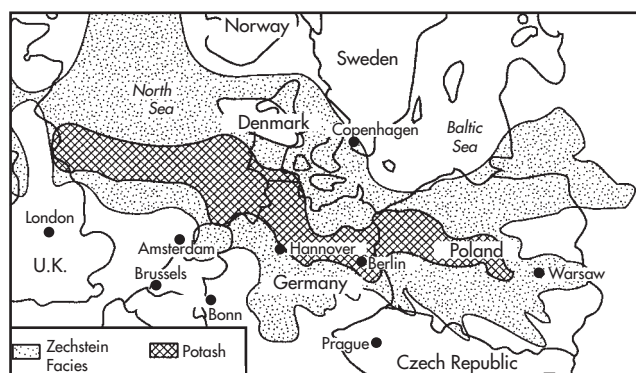

ated mineral. A part of the caliche deposits in Chile have minor amounts of potassium nitrate in the ore.

Europe

Commonwealth of Independent States

The CIS has an estimated 3.5 Gt K_2O (32% of the world's potash reserves), which occur in several sedimentary basins (Figure 11). In the Pripjat Depression and the Dnieper-Donets Depression, potash occurs in Devonian age salt. Several potash-bearing salt deposits of Permian age occur in the East European Basin (Zharkov 1984). The Dnieper-Donets Depression also contains Lower Permian Asselian and Sakmarian deposits (Figure 11). Sakmarian salt also is found northeast of Moscow in the Moscow Basin. The Caspian Depression contains Kungurian deposits that also occur in the Belsk and Solikamsk depressions of the Cis-Uralian trough. The thickest salt strata with potash salt horizons occur in the Kungurian deposits. In the late 1980s, one mine was lost to flooding in the Berezniki Area of Perm, but sylvinitic ore from another mine kept the beneficiation plant operating.

Belarus. In the Pripjat Depression, four potash horizons were identified in the lower salt sequence of the Liven horizon of Devonian (Frasnian) Age (Zharkov 1984). Potash horizons range from about 130 to 1,500 km^2 . They contain beds of sylvite with minor

Adapted from Zharkov 1984.

Figure 12. Lithologic map of Permian Zechstein 3 evaporite deposit

carnallite in beds 4 cm to 1.5 m thick interbedded with muddy halite. Above the salt of the Liven horizon, 60 potash occurrences were identified in the upper salt sequence in the Elets horizon (Famennian). Potash occurs in an area of about 5,000 km² at depths varying from 200 to 3,000 m on local uplifts. Potash-bearing halite occurs in the upper part of the sequence in zones of sylvite as thick as 70 m, interbedded with halite. Major potash production is from the Elets horizon at an average depth of 480 m; potash ore grade is about 18% K₂O.

Kazakhstan. Kungurian (Lower Permian) salt in the Precaspian Depression contains polyhalite–halite, bischofite–carnallite, carnallite–halite, and sylvite–halite rocks. The salt sequence was studied in more detail on the flanks of the Precaspian Depression. In the center of the depression where the salt is strongly deformed, drill holes in several salt domes explored for potash salts or other mineral resources.

Russia. The Permian salt in the Solikamsk Depression is found in the Iren horizon of the Kungurian stage. The potash member is divided into two intervals: the lower sylvinite and upper sylvinite–carnallite. Average thickness of the lower interval is about 21 m; the upper interval averages 60 m. Deposits are generally medium grade (16% to 23% K₂O), occurring at depths between 200 and 500 m.

Siberia. Cambrian salt covers an extensive area in eastern Siberia. Potassium salts occur in the Chara horizon (Lower Cambrian), where three sections are distinguished: carnallite, sylvite–carnallite, and sylvinite. The potash horizon lies at depths of 600 to 900 m and contains some sylvite ore grades that are more than 30% K₂O. Currently, there is no production in Siberia.

Ukraine. In western Ukraine, low-grade potash deposits were mined from Lower and Middle Miocene rocks near the Stebnik and Kalush-Golyn regions (Kopin 1963). The first three of four evaporite cycles contain individual beds of langbeinite, kainite, and langbeinite–kainite with minor chlorides, and also beds that contain sylvinite, carnallite, kainite, langbeinite, schoenite, and polyhalite. The percentage of insoluble residues is high, averaging between 9% and 14% K₂O in the langbeinite–kainite ores to as much as 33% in the sylvinite ores. The fourth evaporite cycle contains polyhalite, but it has no soluble potassium salts.

Low-grade potash ore also was recovered from the Kramatorsk Formation of probable Sakmarian age in the Dnieper–Donets Basin. Interbeds of sylvinite, carnallite, carnallite–halite, and sylvite–carnallite occur in the upper part of the formation. Potash salts form two horizons: the Privolno sylvinite horizon and the upper Chasov-Yar sylvinite–carnallite horizon.

England

The Boulby mine in England has produced potash from sylvinite beds in the English Zechstein Basin since 1973. Two sylvinite beds averaging 6 to 8 m in thickness occur at depths between 1,000 and 2,700 m. Underground facilities suffered from water inflow, affecting production in the late 1990s. Potash production capacity in 2004 was estimated at 600 kt K₂O.

France

Potash was mined in France until 2002, when the economically viable potash ore was depleted. The principal potash reserves of France were in evaporates, deposited in the Oligocene Rhine graben. Potash salts occur in the subsurface at depths from 420 to 1,100 m in two laterally continuous zones in the upper third of the evaporite section. The lower potash interval, which contains sylvite with some carnallite, is up to 5 m thick. It is separated from the upper sylvite zone, which ranges up to 2 m thick. The ore contains several bands of claystone that impart a high content of insolubles. Dips of more than 10° are common, and mining was by longwall rather than room-and-pillar method.

Germany

The largest production comes from the Permian Zechstein, where the world's first subsurface potash occurrences were discovered (Figure 12). The Zechstein contains four evaporite cycles with the lower three containing five potash horizons: Thuringen, Hessen, Stassfurt, Ronnenberg, and Riadel. The Hessen and Thuringen horizons are mined for carnallite and hartsalz. The latter is potash ore containing sylvite and kieserite, a relatively hard mineral. In the Werra-Fulda District, these deposits are mined at depths of 400 to 1,000 m. Beds are flat-lying and relatively undeformed; the potash is of uniform grade and distribution, permitting room-and-pillar mining. Potash deposits in the Hannover District are on steeply dipping flanks of both conformable and piercement salt structures. Mining is by stoping and backfilling, and is concentrated between depths of 300 and 800 m. The ore is irregular and discontinuous, and requires underground exploration drilling.

Mining in the Stassfurt District also exploited potash reserves of the Zechstein salt until 1972. During a restructuring of the German potash industry in the early 1990s (following reunification of East Germany and West Germany) five mines were closed because of low ore grade or problems of mine waste disposal. By 2004 the total production capacity of potash operations in Germany was estimated at close to 4.3 Mt K₂O.

Italy

Potash mines on the island of Sicily extracted kainite from the Solfifera Series of Miocene age. The only other known kainite reserves are found in Ethiopia and Ukraine. Kainite from Sicily was used in the manufacture of potassium sulfate. The potash operations shut down during the mid-1990s. Other minerals present in the Solfifera were carnallite with some sylvite, kieserite, and bischofite in beds 2 to 30 m thick with dips up to 60°.

Poland

In Poland, potash deposits are known to occur in the Zechstein in three separate areas (Orska and Werner 1978). In the late 1960s, polyhalite deposits were found in the Puck Gulf region along the Baltic Sea. According to Werner (1975), one drill hole intersected 6.5 m of nearly pure polyhalite at a depth of 788 m. At present, there is no development of this deposit. Another potash deposit in the Zechstein consists of carnallite and occurs in the Nowa Sol Area, 60 km east of the German border (Orska and Werner 1990).

Spain

Potash mines in northern Spain produce potash from evaporites of Late Eocene to Early Oligocene age. In the Navarra mining district, potash occurs at depths of 120 to 600 m in two beds: a lower sylvinite bed and an upper bed, which is principally carnallite. Carnallite and sylvinite deposits in the Catalonia mining district occur in four folded and deformed beds. Mining beds that dip at 30° are common.

Africa and the Middle East

Egypt

The Red Sea rift zone contains thick Miocene evaporites that extend northwest into the Gulf of Suez region. Potash minerals, including sylvite, polyhalite, and langbeinite, were identified in side wall cores from petroleum exploration wells in the Gulf of Suez (Hite and Wassef 1983). Correlations in the thick sequence of evaporites in the Zeit and South Garib formations show that millions of tons of polyhalite occur in the Suez Area (R.J. Hite, unpublished data).

Ethiopia

Potash deposits in the Danakil Depression of Ethiopia are young (Quaternary) and contain extensive kainite beds. Potash occurs in three members in the Houston Formation: the uppermost sylvinite member, up to 10 m thick; the intermediate member, 3 to 24 m thick containing carnallite throughout with sylvite at the top and kainite at the base; and the Lower Kainite Member, 4 to 13 m thick. The deposit is in a salt pan in a rift valley depression characterized by recent volcanism and high heat flow (Holwerda and Hutchinson 1968). Several hot springs and brine pools are found in the salt pan; groundwater in sedimentary units interbedded with the evaporites is a potential hazard for underground mines. Several companies explored the deposit in the 1960s and 1970s. In 1973, exploratory drilling and mining ended after an overlying water-bearing alluvial fan caused flooding in the mine.

Israel and Jordan

Israel and Jordan are the only major producers of potash in the Middle East. Potash is produced from brines of the Dead Sea, which contains 980 Mt K₂O (Neev and Emery 1967). Both countries use solar evaporation ponds along the margins of the Dead Sea to recover carnallite, which then is converted into potassium chloride. In 2004, their combined potash production capacity was estimated at 3.4 Mt K₂O.

The Dead Sea rift zone also hosts several salt beds beneath the floor of the Dead Sea. These contain potash deposits originally discovered by petroleum exploration wells.

Morocco

The Moroccan Meseta basins contain Late Triassic sylvite–carnallite deposits with bischofite and rinneite (FeCl₂•NaCl•3KCl). Potash salt deposits, interbedded with basalt flows (Tortochaux 1968), occur at depths between 490 and 790 m. The sylvinite bodies are low grade and erratic.

Republic of the Congo

Potash production started in 1969 at Holle, 40 km northeast of Point Noire. Cretaceous potash beds contain sylvite and carnallite. Irregularities in the potash beds initially caused difficulties for boring machines. When a mining machine opened a brecciated collapse column connected to an aquifer in 1977, the Holle potash mine was lost after it abruptly flooded. Since then, a few studies evaluated the feasibility of renewing mining operations in the district. In 2004, MagMinerals Inc., a subsidiary of Canada-based MagIndustries Corp., announced its plan for the construction of a

solution mining operation and a magnesium plant complex that would use potassium brines from the Kouilou salt deposits.

Saudi Arabia

In the Red Sea rift zone, thick (up to 3,000 m in cores) and extensive Miocene evaporites occur near the surface in a group of salt domes in the Farasan Islands along the west coast of Saudi Arabia. Minerals include bischofite and only minor carnallite.

Asia

China

Although China has been mining and exploring evaporite deposits for nearly 2,000 years, only minor amounts of potash have been discovered. The most extensively explored basin is in Sichuan where brines from Triassic evaporites produced potash for many centuries. The brines produce sodium chloride primarily, but small amounts of other by-products, including potash, also are recovered. The Triassic halite deposits in this basin locally have bromine values as high as 300 ppm, and so the Ministry of Geology and Mineral Resources (MGMR) concentrated most of its exploration efforts in this basin. No economic concentrations of potash were discovered other than minor amounts of polyhalite. Sylvite deposits are found in rock salt mines in the Simao Basin in Yunnan Province. The evaporites occur in rocks of Middle Jurassic, Late Cretaceous, and Paleocene ages. Although their precise age is unknown, it seems likely that the Simao Basin evaporites are the same age (Cretaceous) and occur as a northern extension of the potash-bearing evaporites of the Khorat Plateau of Thailand and Laos. The Yunnan sylvite deposits are lenticular and have a high degree of deformation. Ore grade seldom exceeds 15% K₂O. Because of the lenticular nature and deformation, low grade, and extremely remote location of the sylvite, the government does not consider this area worthy of further exploration.

Currently, most potash production in China comes from a large salt lake in the Qaidam Basin in Qinghai Province. In 2004, potash production occurred at more than 30 operations; production was estimated to exceed 1.2 Mt K₂O from the solar evaporation of carnallitic brine.

China's need for potash is acute. Over the centuries, soils in China's principal farming areas were depleted in potash because of continued agricultural use. Potash consumption was 0.5 Mt K₂O in 1986; it reached 4.9 Mt K₂O in 2004. The global ratio of N:P:K applied to agricultural lands is 1.0:0.45:0.36, but in China the nutrient ratio in 2004 was 1.00:0.39:0.19, compared with 1.00:0.19:0.03 in 1986.

Pakistan

The Salt Range in West Pakistan has a thick sequence of Lower Cambrian evaporites that include some potash. The evaporites are near the surface at several localities along where they are mined for their halite content. At Khowra and elsewhere, the potash occurs and is exposed in rock-salt mines in 10 discrete zones or deposits (Jones 1970). The potash minerals include langbeinite, kainite, sylvite, and polyhalite.

Thailand

Potash deposits are present in the Maha Sarakham Formation (Cretaceous) on the Khorat Plateau of northeast Thailand and eastern Laos. They occur in the lowermost of three thick halite deposits. A northwest-trending uplift (Pu Phan) divides the deposits into a southern basin (Khorat) and a northern basin (Sakhon Nakhon). Because the evaporite stratigraphy is identical in either basin, the uplift probably formed after deposition of the evaporites. The base

of each evaporite sequence in both basins is undeformed, but the tops are folded into numerous salt anticlines and domes. Most of the potash consists of carnallite, as much as 95 m thick (Hite and Japakasetr 1979). This is carnallite deposit, thought to be primary, also contains the highly soluble mineral tachyhydrite. Locally around the anticlines and domes, meteoric waters altered the carnallite deposit into lenticular bodies of high-grade sylvinite (Hite 1982). The Thailand Department of Mineral Resources did most of the exploration, although concessionaires also performed some drilling in recent years. The government of Thailand planned to exploit the carnallite deposit near Bamnet Narong; in 2004, however, the Ministry of Industry announced that the Thai government had withdrawn its financial support for the ASEAN Potash Mining Co.'s potash mining project in Bamnet Narong. Since 1990, Asia Pacific Potash Company (APPC), a subsidiary of Asia Pacific Resources, has carried out an extensive exploration program and completed feasibility studies for the development of an underground potash mine and the construction of beneficiation facilities. APPC holds prospecting licenses for two large sylvinite-bearing potash deposits in the Sakon Nakhon basin. In May 2003, APPC filed a mining lease application for its Udon South potash deposit (the "Somboon" deposit) near Udon Thani in northeast Thailand. The company is hopeful that it will obtain the mining license in 2006 and start potash production by 2009.

Oceania

Australia has several large salt basins, but no economic occurrences of potash have been discovered. In the Carnarvon Basin, minor occurrences of sylvite have been observed in petroleum test holes in a Silurian halite deposit. In addition, three petroleum tests drilled in the Adavale Basin found potassium minerals, mainly sylvite, in the Etonvale Formation (Devonian).

PRODUCTION TECHNOLOGY

Mining

For underground mining of sylvinite, ore grade should be 14% K_2O or higher, and bed thickness should be 1.2 m with about an 8-m-thick salt back (or roof). The USGS established the 14% K_2O rule in Carlsbad, New Mexico, in the early 1930s; East Germany and Russia however, mined potash ore as low as 11% K_2O while operating under centrally planned economics. Carlsbad potash (sylvite) producers have operated with 80% to 85% recovery in the mill (some producers operate at 92% recovery by pulling pillars). French and British operators installed crystallizers to the back ends of the mills to capture potash from waste liquor before sending the liquor to the tailings piles with waste salt. This is an additional step raised recovery at their plants to as high as 92%.

The proved amount of ore for a new mine should confirm a minimum of 20 years of production given mill size, mill recovery, and the underground recovery factor for ore depth. Plant or mill size should be at least 300,000 t K_2O to compete in a market that has many plants in the 1-Mt K_2O size. This is the economies-of-scale concept expressed by economists. The existence of "salt horses" in the ore zone is another factor to consider (Jones and Prugger 1982). In Saskatchewan, these barren patches of almost pure halite can constitute as much as 10% of the ore and require additional monitoring of the mining operation.

Conventional North American mining methods illustrate two extremes for percentage of underground recovery. Carlsbad mines operate at a depth of about 270 m, with one mine sloping down to 430 m. These mines recover about 75% of the ore on the first pass, and attain 90%, sometimes with surface subsidence, on the retreating pass. In contrast, the mines in Saskatchewan normally are oper-

ated between 1,000 and 1,100 m with a 35% to 45% recovery. Mines in the Patience Lake Member recover about 35% to 40% of the ore whereas mines in the Esterhazy Member, which has at least 18 m of competent salt back above the ore zone, recover about 45%. The Canadian operations do not have a retreating pass. After the original pillars collapse enough for waste heaps to take up the weight of the back (roof), miners return and mine the pillars. This provides a higher underground recovery. Another example of a mine operating at a lower recovery rate is the Boulby mine near Whitby, England. This mine is at a depth of about 1,100 m and achieves around 35% underground recovery.

Much sylvinite mining is now mechanized, using boring machines, drum miners, or longwall miners and occasionally road headers. Boring machines in Canadian mines can continuously produce 12 t/min, occasionally producing up to 17 t/min for as long as 8 hr. Mining machines take the central 3 m of high-grade ore. Mine depths of more than 1,000 m in a sedimentary sequence require sophisticated techniques that sometime involve controlled collapse of panels. All borers feed directly onto conveyor belts connected to main haulage ways or over-bridge conveyors that are connected directly to the conveyor belt system (Jones and Prugger 1982). Drum miners are converted to continuous miners with the addition of bridge conveyors for direct connection to main conveyor belts. In France and Belarus, longwall mining has been used for higher underground recovery and continuous mining. The longwall conveyor belt discharges to a ladder-chain conveyor on the floor of a development roadway at one end of the longwall panel. The ladder-chain conveyor discharges onto the conveyor belt leading to the skips of the ore hoist. Road headers typically use shuttle cars to connect to the conveyor belts but can be connected directly. The Carlsbad mines that recover langbeinite still must use jumbo drills, undercutters, blasting, mucking, and shuttle cars because of the hardness of the ore.

Borers mine ore in very long galleries to take advantage of their cutting method, rather than room-and-pillar, which is the method used with drum mining. Some Canadian mines produce 1,200-m-long galleries with longwalls in between. Other Canadian mines use panels having five entries per panel, with the outer two entries collapsing in 1 or 2 days. Sylvinite and langbeinite mining in Carlsbad is room-and-pillar. The Boulby mine on the eastern coast of England drives five panels with crossovers in a V shape to redistribute the stress.

Where ore zones are not flat-lying, other methods of underground mining are used. PotashCorp at its underground operation at Penobscis, near Sussex in New Brunswick, Canada, mines with road headers in a cut-and-fill technique up one side of an anticline. Provincial environmental regulations require that no tailings pile remain on the surface, so all tailings are backfilled into the mine using a second conveyor belt system. Some German potash mines use block-caving (bench-mining and funnel-stoping) methods because potash ore is on the flanks of salt domes.

Solution mining can substitute for conventional shaft mining in potash deposits that occur below approximately 1,100 m, but it is not an alternative for some potash zones too deep for conventional mining methods. Thickness, mineralogy, and structure of the deposit, as well as technical considerations of the mining operation, must be evaluated to determine the suitability of solution mining. Two forms of solution mining are practiced today. A site that was mined initially by conventional underground methods can be converted to solution mining to recover ore that remains in the pillars. Pipes are drilled down to meet the former underground galleries providing communication between an inlet pipe that supplies undersaturated brine to the ore zone and a return pipe that brings

saturated brine to the surface. This method is effective in relatively thin ore zones, for example, those slightly thicker than 1 m. The Intrepid mine at Moab, Utah, was the first to employ this type of solution mining in 1971. Boreholes were drilled to the lowest point in the mine and to all the highest points in the branch galleries. Boreholes in the branch galleries supplied fresh water, and the lowest point in the main gallery became the return pipe for the dense brine. The lower elevation of the return pipe allows only saturated brine to come up from the ore zone, whereas in a flat-lying ore zone it would be difficult to prevent the less dense, undersaturated brine from returning to the surface. PotashCorp converted the Patience Lake mine to a solution mine in 1988 after it was flooded by water coming from a breccia that occurred downdip from the ore zone. Heated brine, which was nearly saturated with respect to NaCl, was then introduced into the mine. The brine dissolved only potash for return to the surface ponds. The imposed hydrologic head prevented most of the less-concentrated brine from the intruding aquifer from entering the mine. Mosaic Company (formerly IMC Canada) operates the largest solution mine in the world at Belle Plaine in Saskatchewan, Canada. In 2004, the facility had a production capacity of more than 1.7 Mt K₂O.

Solution mining with concentric pipes solves the problem of establishing communication between the inlet and the return pipe. Three concentric pipes are required: the innermost and the deepest for the return flow, and the middle for the inlet flow of hot NaCl-saturated brine. The outermost concentric pipe injects oil, which floats above the brine, to force the injected water to mine outward instead of upward around the pipe. A large diameter for the cavity must be established, and it is critical that the potash zone or sequence of zones be sufficiently thick. Development of mine production by this technique generally requires that the cavity have enough potash to pay for drilling the well, for the equipment in the well field, for the pipes leading to the crystallizers, and for all recovery plant costs.

Solution mining also is used in shallow, high-grade deposits where structural complexity precludes successful underground mining by conventional methods. Conversion to solution technology at the mine in Moab was dictated by the high degree of structural deformation of the ore layer, a problem that was not indicated by the original exploration drilling (Evans and Linn 1970). Solution mining initially was quite successful because of the large surface area of potash ore in the original room-and-pillar structure. The K₂O content of the brine pumped to the surface has diminished continuously with removal of the mine pillars, and there is little indication of active dissolution of ore beyond the original mine workings.

Processing and Beneficiation

In operations where potash reserves are surface or subsurface brines, or where ore is extracted by solution mining, potash must be recovered with technologies specific to brines. Three processes currently used for performing this recovery are crystallization of potash by solar evaporation, by reduction of brine temperature, and by artificial processing through crystallization–evaporation cycles. Each process uses selective dissolution and precipitation of sylvite from brine. Where brine is saturated mutually with KCl and NaCl, the solubility of NaCl decreases slightly with increasing temperature up to 90°C, above which the solubility of NaCl then increases with temperature. Because the solubility of KCl increases dramatically up to 90°C, a warm brine would dissolve much less NaCl if there were sufficient sylvite available to saturate the solution with respect to KCl. When the brine is cooled, sylvite precipitates more rapidly than halite, and, at certain temperatures, a solution saturated

with respect to both KCl and NaCl precipitates only sylvite; the NaCl remains in solution.

Climate is extremely critical for effective solar evaporation from surface ponds. Brine brought to the surface at the Moab mine evaporates completely in single ponds to precipitate a mixture of sylvite and halite. Dyes added to pond brines increase solar energy adsorption and so increase brine temperature and rates of evaporation. The operations at Ogden and Wendover, Utah, use lake water or near-surface brines and multiple ponds. Multiple ponds are used to establish brine densities for crystallization of various minerals at different stages. Efficient solar evaporation occurs during only 3 months of the year (June, July, and August), with more than half the total evaporation occurring in July. During this 3-month period low rainfall must combine with sufficient wind to keep the brine mixed and to enhance evaporation. At Moab and Wendover, both sylvite and halite precipitate out of solution in the potash-harvesting ponds. The harvest then is sent to a standard flotation-type beneficiation plant to separate the two salts.

Two potash operations at the south end of the Dead Sea benefit from a climate that promotes evaporation throughout the year. During evaporation of the Dead Sea brine, carnallite and halite precipitate out of solution in harvesting ponds. MgCl₂ is washed away with freshwater, leaving a mixture of sylvite and halite. On the Israeli side, sylvite is separated from halite in three different processing plants. The oldest plant uses flotation technology. A capacity expansion added a process that uses dissolution–recrystallization. The newest plant uses a proprietary cold-crystallization process that uses a low-heat crystallizer to produce KCl.

The solution mine of PotashCorp in Patience Lake, Saskatchewan, uses a selective precipitation process that takes advantage of natural cooling. One large pond operates from September through May. As warm brine from the mine flows into the pond, only sylvite crystallizes on exposure to the cold winter air. Then the pond is dredged and the precipitated sylvite is dried for marketing. The process is predicated on the temperature dependence of NaCl and KCl solubilities.

Another method of recovery is used by the Mosaic Company in Belle Plaine, Saskatchewan. The brine is processed using two trains of evaporators and crystallizers. Evaporators remove NaCl from the brine and KCl precipitates in the crystallizers.

Ore beneficiation methods also differ according to the type of ore. For less-soluble ores such as the langbeinite mined in the Carlsbad area, leaching is an effective beneficiation method for ore grades at about 9% K₂O. One of the two processes involves preferential dissolution of associated salts (mostly halite with a little sylvite) from the ore. The other process uses heavy media separation and flotation in addition to leaching. Gundiler (1999) reviews processing technology at the Carlsbad potash district.

The potash industry began using flotation technology for sylvite in the early 1930s in Carlsbad. The use of flotation gradually spread to France, England, Germany, the CIS, and Israel. After the slimes (clay and hematite) are washed away, the pulp (the suspension of crushed sylvite in saturated brine) is treated with a long-chain amine (C-18 to C-22) and a frother (such as pine oil). It is then passed to an agitation cell where compressed air is introduced from the bottom. A froth of amine and entrained air bubbles carries the potash to the surface, where it is mechanically swept over the side of the cell into a trough. Carnallite is avoided during mining because it has a detrimental effect on flotation cell recovery (Jones and Prugger 1982).

The Mosaic Company uses heavy-media technology in its plants in Saskatchewan. Sylvite and halite crystals of the Esterhazy zone are crushed to 1 cm and separated by heavy media using the

Table 6. Product specifications

Grade	Minimum K ₂ O Equivalent, %	Approximate Particle Size Range*		Type of Potash
		Mesh†	mm	
Granular	60, 50, 22	6–30	3.34–0.85	Muriates, sulfates, and magnesium sulfates

‡ NA = not applicable.

small-density difference between halite and sylvite. In Carlsbad, one heavy media circuit separates sylvinites and langbeinite, then a second heavy-media circuit separates sylvite and halite.

In the early 1910s, the French developed dissolution–recrystallization technology at their former operations for processing potash ore with high insoluble content. The first Carlsbad potash mill also used this technology but converted to flotation when it became obvious that the latter would clean sylvinites ore (<3.5% slimes). One Carlsbad mine continues to use the dissolution–recrystallization technology for ores with >5% slimes content.

Electrostatic separation of potash was first investigated in Carlsbad after World War II, but it was not implemented. It was resurrected in Germany and, after years of development, proved to be a low-cost, high-volume process (Singerwald and Neitzel 1983). The waste product is dry, there are no waste brine disposal problems, and little heat input is required of the operation. The process involves moderate heat, reagent coating, a source of electric power, and careful control of relative humidity in the separation chamber. Separations can be serialized in a multistage process line.

Potash Products

The fertilizer trade refers to potassium chloride as muriate of potash (MOP), potassium sulfate as sulfate of potash (SOP), and potassium magnesium sulfate as sulfate of potash-magnesia (SOPM). About 96% of potash used for fertilizer is in the form of MOP; the remainder in the forms of sulfates and nitrates (Searls 1985). Lixivation is used for production of potassium sulfate. The process starts with kainite, either mined or crystallized from lake brines. Kainite is converted to schoenite ($\text{MgSO}_4 \cdot \text{K}_2\text{SO}_4 \cdot \text{H}_2\text{O}$), and potassium sulfate is crystallized from the schoenite. An other method of beneficiation of potassium sulfate is through ion exchange.

SOP does not occur naturally. Most commercially produced SOP is synthesized by heating MOP and H_2SO_4 to approximately 650°C in large furnaces. Some German potash mines produced SOP by combining kieserite ($\text{MgSO}_4 \cdot \text{H}_2\text{O}$) and sylvite (Singerwald and Neitzel 1983). A potash operation plant in Carlsbad produced SOP by mining sylvinites and langbeinites and performing a base exchange (Anon. 1968). Great Salt Lake Minerals & Chemicals Corp. uses solar evaporation to produce kainite ($4(\text{KCl} \cdot \text{MgSO}_4) \cdot \text{H}_2\text{O}$) from Great Salt Lake brines, and beneficiation follows with the lixivation process.

MOP, which constitutes close to 96% of the world's production of potash, has a minimum requirement of 60% K₂O content. SOP has a minimum requirement of 50% K₂O content, and SOPM has a minimum requirement of 19% K₂O content. Table 6 lists product specifications, including various grain sizes of different grades of

potash. Coarse MOP is the most popular size sold in the United States, but granular MOP for use in machine-spread fertilization and bulk blending is a close second. Standard MOP is preferred in countries where fertilizers are still hand cast. Particle sizes listed in Table 6 do not describe fully the current expectations of farmers. Current potash producers claim to match the current particle-size distribution of monoammonium phosphate (MAP) or diammonium phosphate (DAP) particles.

By-products and Coproducts

Typical potash beneficiation is based on flotation technology and generates NaCl as waste. Some waste salt has clay, hematite, and other impurities such as shale. Some potash sources and beneficiation techniques produce a variety of by-products. German mines using electrostatic separation produce magnesium sulfate (kieserite) and rock salt pure enough for road deicing. German mills that use dissolution–recrystallization produce magnesium chloride, salt, and bromine. The Israelis also produce bromine as a by-product. Potash produced from the brines of Searles Lake in California has soda ash and salt cake coproducts. The surface brine at Wendover, Utah, produces salt and magnesium chloride as by-products. Great Salt Lake Minerals & Chemicals Co. produces salt for road deicing, Glauber's salt ($\text{NaSO}_4 \cdot 10\text{H}_2\text{O}$), and magnesium chloride. The solution mine at Belle Plaine, Saskatchewan, produces large amounts of clean salt brine, which is sold to a nearby salt producer. The dissolution–recrystallization mill in Carlsbad, New Mexico, occasionally processes ore that contains some sulfate. The sulfate plugs up the circuit as glaserite (K_3NaSO_4), which is recovered and sold in small amounts as a low-priced substitute for SOP if the crop can tolerate the slight amount of sodium.

ECONOMIC FACTORS

U.S. Historical Consumption

The United States passed through an S-shaped potash consumption curve between 1920 and 1990 (Figure 13) as it learned to feed an ever-growing population. U.S. consumption of potassium fertilizer peaked at about 5.7 Mt K₂O in 1981 and gradually declined afterward to stabilize at about 4.5 Mt annually. In 2004, the overall consumption in fertilizers was estimated at about 4.6 Mt K₂O (Heffer 2004). The decline in potash consumption reflects more efficient use of fertilizers and a decline in crop exports as other countries began their own green revolutions. Generally, the need for fertilizer increases as the population increases, but populations do not buy fertilizer until they can afford it (Figure 14). Many developing countries need fertilizers (in addition to good weather and modern farming practices) but are not able to purchase them until the

Figure 13. History of U.S. potash consumption and growth of wealth

wealth (gross domestic product [GDP] per capita) of the population increases. By grouping countries and taking averages of these groups, one can clearly see in Figure 14 the progression of potash consumption as a function of wealth.

A worldwide overcapacity of potash has forced several potash producers to operate below capacity since 1990. For example, Potash Corporation of Saskatchewan produced well below nameplate capacity during much of this period. U.S. potash companies could not meet current demand in the United States (Figure 15). Potash mines in Canada currently provide more than 90% of the U.S. apparent consumption. U.S. potash producers exported about 23% of their total sales to the Caribbean and the Pacific Basin. Transportation costs govern much of this export routing. Table 7 shows world potash mine production for 2004.

U.S. Prices

Prices for commodities are hard to define because many firms sell at slightly lower prices to large-volume buyers. Large-volume buyers also may receive extended terms, the period allowed for the buyer to pay without interest penalties. Terms may be 30, 90, or even (rarely) 180 days. Prices reported by the USGS represent the average annual prices received by U.S. potash producers, free on board (f.o.b.) at the plant; annual prices are computed by dividing total dollars received by tonnage sold (Searls 2005). The average for U.S. producers includes all types of potash (MOP, SOP, and SOPM) for all grades (sizes). Large-size particles command a premium price in the United States.

Other

Prices can be quoted for standard MOP, f.o.b. Vancouver, British Columbia, Canada. Prices around the world tend to be set by firms or countries by summing the Vancouver price and the transportation cost from Vancouver to a port of competition, then backing out their own transportation cost to that port of competition.

Transportation

Deepwater transportation prices rise and fall with the overall supply and demand for all types of ocean shipping. As an example,

Figure 14. Relationship of wealth to consumption of potash

Figure 15. Components of U.S. supply and demand for potash

Table 7. World potash production for 2004, kt K₂O equivalent

Country	Production	Country	Production
Belarus	4,610	Israel	2,140
Brazil	370	Jordan	1,160
Canada	10,100	Russia	5,600
Chile	520	Spain	550
China	1,050	United Kingdom	540
Germany	3,630	United States	1,200

Adapted from IFA (Potash Statistics 2004) and Searls 2005.

between April 2002 and April 2005 international maritime freight rates increased fivefold. Certain potash shipments move at lower costs because they are backhauls. A backhaul is made when a ship or railcar returns to its origination point with another cargo.

Substitutes

Potassium (K⁺ ion) is essential to plant and animal life, and Li⁺, Na⁺, Rb⁺, and Cs⁺ are not substitutes. Potassium is essential to protein synthesis in plants, and it specifically activates the enzyme responsible for starch formation. In humans, K⁺ ions and Na⁺ ions in nerve sheaths are the essential sodium pump that allows signals to travel along nerve pathways. Potash is the low-priced, water-soluble form of K⁺ ions available at this time. For plants, green manure is a

substitute but only near farms that fatten beef and raise pigs, chicken, sheep, and dairy cattle. Green manure does not contain enough potash to transport over distances >80 km. MOP is concentrated enough to ship a few thousand kilometers. Greensand (glauconite) is used by organic farmers if it is available. Greensand contains up to 7% K_2O , but it is shipped long distances because it contains some phosphorus and because it meets the requirement of organic farmers for natural fertilizer, for which they are willing to pay extra.

For industrial uses, NaOH (caustic soda) substitutes for KOH (caustic potash) because of its wide availability and lower cost. Potassium nitrate or potassium carbonate impart different optical, density, and luster qualities to certain glasses, making them desirable to glass manufacturers. Potassium carbonate is used in chocolate and cocoa manufacture, liquid soaps, welding rods, vat dyeing, photographic chemicals, electroplating compounds, fire extinguishers, and rubber antioxidant applications. In smaller amounts, it is used in many consumer end products.

GOVERNMENTAL CONSIDERATIONS

Environmental Regulations

Activities of the potash mining industry may result in a wide variety of environmental effects. Typically these are quite localized and confined to the mine site in most cases. At any specific site the type and extent of environmental effects depend on factors such as mining methods, beneficiation processes, waste disposal methods, and proximity to existing population centers and infrastructure.

Underground mining methods tend to create fewer environmental problems. A major issue is possible surface subsidence induced by the removal of extensive flat-lying ore deposits. Water quality also may be affected by release or leakage of slurry brines and contaminants into process water. The land surface and subsurface are disturbed by mining extraction methods, deposition of overburden, disposal of beneficiation wastes, or surface subsidence. Environmental impacts caused by handling, such as dust and exhaust emissions, tend to be local. Dust may be generated from traffic on unsealed roadways, from loading and unloading operations, from conveyor transfer points and stacking stockpiles, and from reclamation operations. In Carlsbad, New Mexico, dust emissions were once an issue; in recent years, however, a variety of baghouse and wet scrubber emission-control equipment was installed throughout ore-handling and processing facilities.

Large volumes of waste tailings generated from beneficiating potash potentially may generate harmful environmental effects. Wastes can comprise impure salt, slimes, clay, dolomite, anhydrite, and other salts such as magnesium chloride. The potash industry uses a wide variety of waste disposal methods such as discharge of wastes into rivers and oceans, pile stacking, backfilling of solid and liquid wastes into mined-out underground openings, or deep-well injection of brines.

In Germany, potash mining generates 0.78 t of waste per ton of beneficiated ore; these wastes consist of salt and magnesium chloride brines. Brines are disposed by either deep-well injection or discharge into the Werra and Ulster river system. A computer system monitors and controls the discharge to ensure that the maximum permitted salt concentration of 2.5 g/L of river water is not exceeded as river conditions and flow rate vary. This system prevents adverse environmental effects in the riparian and aquatic ecosystems downstream.

Tailings are designed as integrated systems comprising engineered impoundments, walls, containment dykes, liners, drains, ditches, and capture wells. In Saskatchewan, salt wastes typically are disposed of as slurry on the tailings pile. Insolubles and brines drain into the settling ponds at the base of the pile. The brine is then

either recirculated into the process or disposed of through deep-well reinjection. In Germany, dry separation processes allow dry disposal on a salt tailings pile.

Backfilling of mine and process wastes into underground openings is conducted at a few operations. The technical feasibility of backfilling mines in flat-lying ore bodies was studied in large-scale trials, but it was hindered by the difficulty of placement, safety concerns, and cost. Currently, the cost of backfilling these spaces may be 10 times greater than the cost of surface disposal methods. Deep-well injection is used to dispose of brines at some operations. PotashCorp's New Brunswick Division operation uses effective and environmentally sound waste management by returning all waste to underground workings using a closed-loop system. This system returns all waste slimes and brines underground through a slurry pipeline into the excavated salt rooms. Clarified brine is recovered from the salt rooms and returned as input to the crystallization circuit for recovery of residual potassium chloride. The water balance of the operation essentially is a closed system.

Surface- and groundwater contamination can occur through the release or seepage of tailings effluent and brines from dams, ponds, and stacks. Leakage of liquid wastes such as brines from storage and disposal ponds is controlled to a large extent by containment techniques such as plastic or clay liners, ditches, drains, and containment pumping wells.

A number of companies have conducted trials to determine the feasibility of sealing the surface of potash salt tailings piles to isolate the salt from the environment, to allow the establishment of vegetation, and to leave a stable landform. In Germany, rehabilitation of a small tailings pile of less than 11 Mt of waste salt began in 1997 by capping it with demolition rubble from the City of Hannover. Then the salt tailings pile was covered with soil (as a growing medium) for revegetation. In France, the closure of the potash operations led to a vast rehabilitation program of the salt tailings. One method consisted of capping the piles with plastic, clay, or bituminous liners; covering them with a growing medium; and revegetating with grasses. The other method involved dissolving the salt component in the pile using fresh water and discharging the resulting brines in a controlled manner into the adjacent Rhine River.

For a comprehensive discussion on environmental aspects of potash mining, see UNEP/IFA (2001).

SAFETY AND HEALTH CONSIDERATIONS

Because potash mines are in sedimentary deposits along with oil and gas, and most potash mines were discovered through oil and gas exploration, some potash mines contain high amounts of methane gas. Recovery in these mines requires special precautions and expensive equipment, but these deposits are minable and have good safety records. Scaling the mine roof is a constant concern in some potash mines. Mud seams often are associated with, or are directly above, potash zones; often the level of the cut is gauged by these mud seams. In the Esterhazy ore zone in Canada the mud is present as a thin band in the middle of the highest quality ore. This band of mud can be seen only by holding a miner's lamp to the face of the ore and watching for the disappearance of the halo around the lamp. In other potash ore zones, mud bands are too few or too thin to be recognized during mining and are insufficient to provide additional support to the potash beds. There is little adhesion between sylvinite and clay, and roof falls may take place causing potential injuries. In some mines in Carlsbad, New Mexico, relief holes are drilled at intersections to bleed off any nitrogen that may lie about 1 m above the potash zone. Roof bolts are installed at the intersections for support. Health effects of potash dust were studied at the University of

Saskatchewan (Markham and Tan 1981); investigators noted that chronic phlegm production, mild shortness of breath, and chronic cough were more common in high-exposure groups such as mining crews and screening operators, but that severe respiratory symptoms were rare.

PROBLEMS AND FUTURE TRENDS

Supply

Since the mid-1980s the worldwide market for potash has been in a situation of oversupply. Because of sustained potash demand and increased production and transportation costs, however, the market became tight in 2004, leading to a series of capacity expansions by established producers and exporters.

According to the International Fertilizer Industry Association (IFA), world potash production in 2004 reached 31 Mt K₂O. The world's potash producers reached an average operating rate in 2004 of 83% of capacity, the highest level in the past 10 years. Excluding Belarus, Canada, Germany, the United Kingdom, and Russia, the rest of the industry operated at close to capacity. In the next few years, potash capacity will increase in almost all producing countries. The major projects include expansions at existing mine sites in Brazil, Canada, Germany, Israel, Jordan, and Russia. Future potash prospects include developments in Argentina, Laos, and Thailand. In 2004, the IFA estimated that world potash capacity would reach close to 40 Mt K₂O in 2008. Between 2003 and 2008, additional capacity will exceed 3 Mt K₂O, of which 70% will be located in exporting countries, 25% in China, and 5% in Brazil.

Demand

In the 1980s and 1990s, the world potash market underwent some significant changes, including the break up of the former Soviet Union and the Eastern Bloc; changes in the agricultural policy of the European Union; the expansion of agricultural production in developing countries; and the consolidation of the potash industry in key producing countries. World fertilizer consumption increased steadily during the 1990s but declined in 2000. Global fertilizer demand recovered thereafter and increased at an average annual rate of 2.4% between 2000 and 2004.

In 2004, the FAO forecast world fertilizer demand in 2008–2009 at 160 Mt, which equates to an average annual growth rate of 1.7% between 2004 and 2008; world potassium nutrient consumption was expected to reach 27.2 Mt K₂O, which equates to an annual growth rate of 1.8% over that of 2004.

There are three different regional trends in fertilizer consumption: decline in demand in developed markets such as North America and Western Europe, transitional markets in the CIS and Central Europe, and increased consumption in developing markets such as Asia and Latin America, driven by urbanization and a growing population.

In 2004, the FAO projected a relative tightening of the global potash market from 2004 to 2008. The prevailing global surplus will gradually decline as demand exceeds supply. Regionally, the total requirement for potassium shows a growing deficit in major importing regions. According to the IFA (Heffer 2004), the regional supply/demand imbalance was projected to increase by more than 14% in Latin America, 16% in East Asia, and 21% in the rest of Asia. The total potassium deficit in all importing regions will exceed 17 Mt K₂O in 2008, an increase of 2 Mt K₂O over that of 2004. In the major producing/exporting regions, the surplus is projected to increase in the CIS and West Asia, and to increase slightly in both Western Europe and North America.

Pumice, Pumicite, and Volcanic Cinder

Gordon C. Presley

INTRODUCTION

Pumice, pumicite, and volcanic cinder are volcanic rocks characterized by a cellular structure. They form as gases (primarily water) dissolved in molten rock (magma), generating a froth that cools and solidifies into rigid foam. The cells or bubbles are referred to as vesicles and range in size from a few thousandths of a millimeter to several centimeters. Because of their vesicular character, both pumice and cinder have lower density and higher porosity than most other rock types. As their vesicle walls are broken, sharp cutting edges are continually generated. These properties are the basis for their commercial value as lightweight aggregates, insulators, absorbents, and abrasives.

The terminology applied to volcanic products is imprecise, reflecting to varying degrees the diversity of volcanic rocks, the relative youth of volcanology as a distinct field of study, and customs and practices of commercial trade. In general terms, pumice is light colored (white, gray, pink, pale yellow, or brown) and highly vesicular and usually has vesicle walls that are visibly glassy. Many pumice fragments are light enough to float on water. Pumice is readily cut by steel tools, and some can be crushed by hand. Individual pumice fragments may range from 1 or 2 mm to <1 mm in one dimension. Commercially, finer fragments are called pumicite or volcanic ash. In volcanology, the term *ash* refers to any fragment <2 mm regardless of its composition. Cinder, or scoria, is dark (black, red, brown) with thick vesicle walls that appear dull or stony and that may exhibit iridescence. Cinder typically is heavier than pumice and has a higher crushing strength. In volcanology, the term *scoria* refers to dark vesicular material throughout a wide size range. Common commercial practice is to use the term *scoria* for larger fragments (usually >2.5 cm) and *cinder* for smaller fragments.

GEOLOGY

Composition and Physical Characteristics

Most pumice is silicic ranging from 60% to 70% SiO₂ or dacitic to rhyolitic in composition. Pumice of less silicic composition, including basaltic, is less common, and does not have extensive commercial use. Scoria and cinder are typically basaltic to andesitic with a composition of approximately 50% to 60% SiO₂.

Pumice and cinder may contain phenocrysts of feldspars and various ferromagnesian minerals that crystallized in magma before eruption. Fragments of rock through which the magma has passed

may be entrained in the melt and wall rock may be fragmented and admixed during an explosive eruption. Some scoria fragments have lithic fragment cores. Phenocrysts and lithic fragments can be detrimental in certain pumice products.

Pumice typically has vesicles of <1 mm separated by thin walls. Vesicle shapes include irregular, spherical, elliptical, and elongate to the point of being tubular with a silky appearance (Figure 1). In some pumices the vesicles are interconnected, making the fragments permeable and highly absorbent. In others the vesicles are isolated, forming a highly porous but very impermeable pumice. Floating masses of pumice fragments from the eruption of Krakatoa in 1883 were reported in the Indian Ocean for up to 2 years after the eruption. Vesicles in cinder are larger and range from spherical to highly irregular in shape with much thicker walls and abundant interconnections. Scoria and cinder are typically porous, but heavier, and do not float.

Density and hardness of pumice must be expressed precisely to avoid confusion. Density can refer to the glass itself, the apparent density of the vesicular pumice particle, or the bulk density of pumice in a deposit or in a pumice product. Pumice glass has a specific gravity of 2.5 or more, depending on its composition. Pumice fragments typically have a specific gravity of <1.0. Expressed as density, pumice fragments typically weigh <1 g/cm³. Depending on moisture content, particle density, and particle-size distribution, the bulk density of pumice typically ranges from 500 to 700 kg/m³. Typical bulk densities of cinder range from 700 to 900 kg/m³ for material used as lightweight aggregate. The bulk density of cinder used for highways and railroad ballast can be considerably higher.

Hardness in pumice can refer to the glass vesicle walls, possibly including crystals or lithic fragments, or to the apparent hardness of the particle as a whole, which is more a measure of the strength of the vesicle structure. Pumice glass typically has a Mohs hardness of 5 to 5.5. A pumice particle may have a much lower apparent hardness and be easily cut with a knife or steel saw because the vesicle walls break readily.

Pumice and cinder are primarily pyroclastic (fragmental) products of volcanic eruptions. Several classification systems differing in various details have been proposed for pyroclasts and pyroclastic deposits based on particle size (Fisher 1961; Schmid 1981; Cas and Wright 1988). Generally, particles >64 mm are referred to as blocks or bombs, depending on their shapes. Particles between 64 mm and 2 mm (4 mm in some schemes) are called

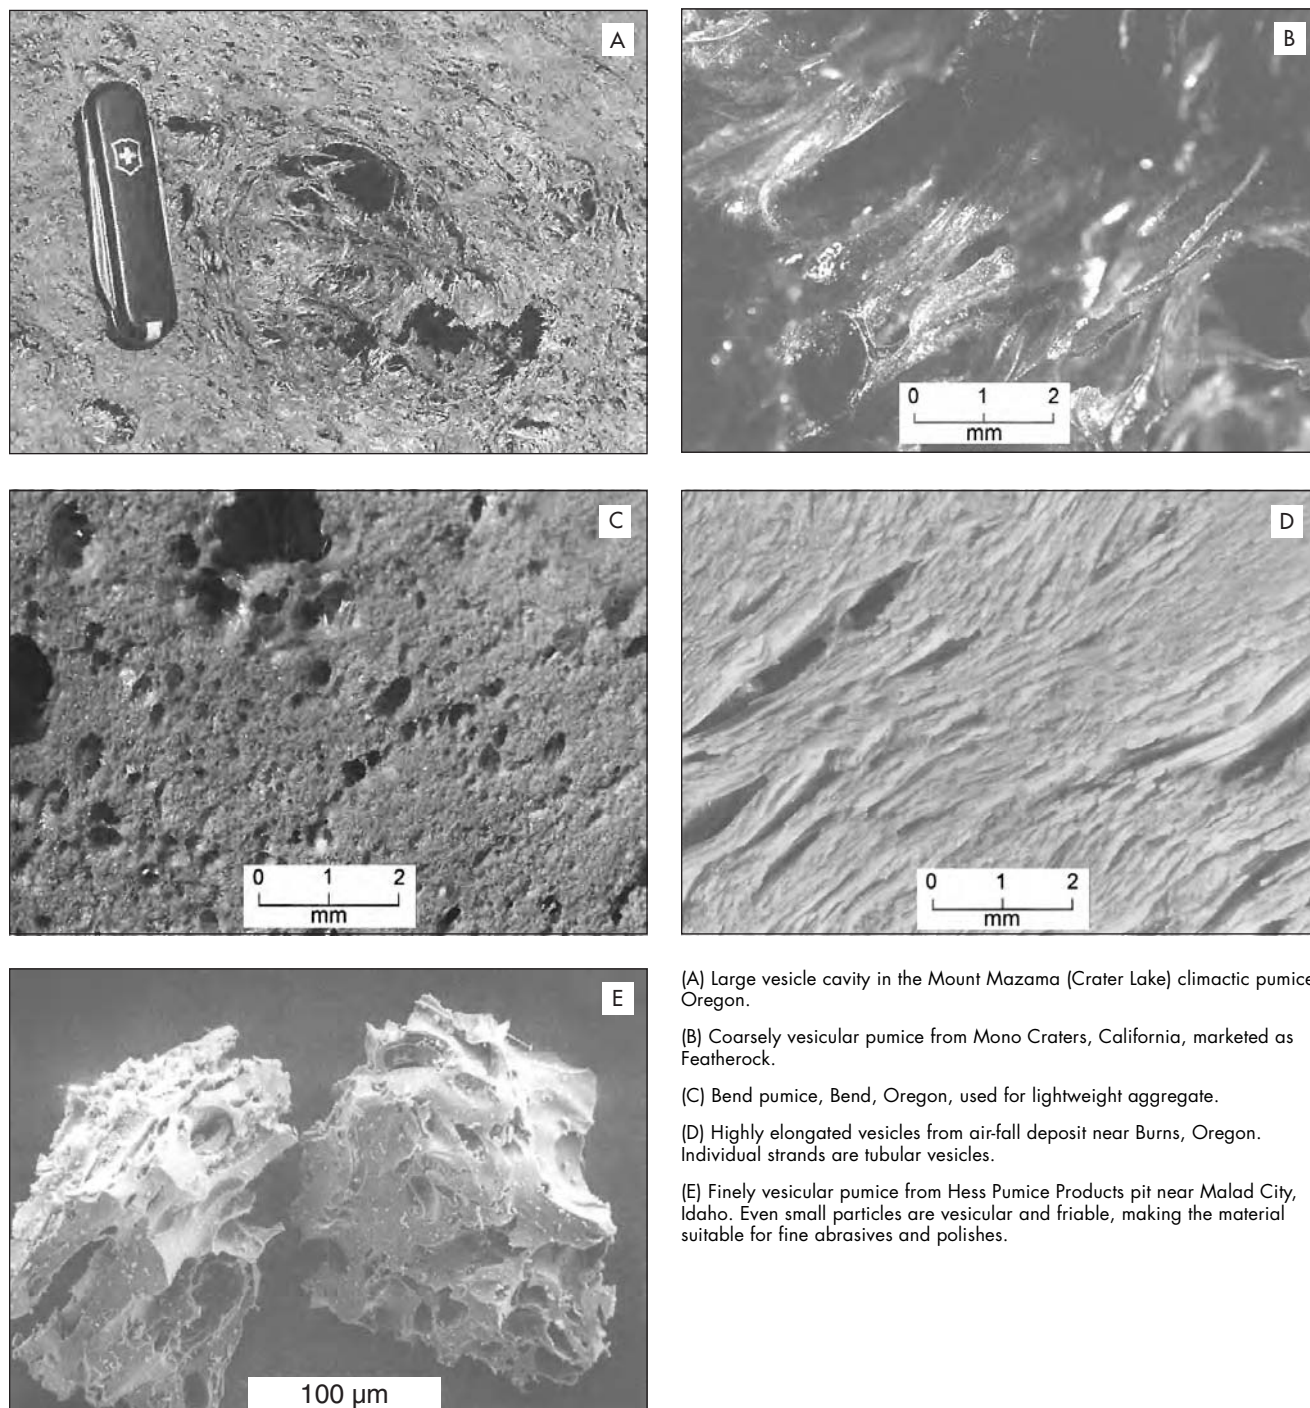

Figure 1. Variations in vesicle shape and size.

lapilli, and smaller particles are called ash. These names may be modified by compositional terms, for example, pumice lapilli or scoria lapilli. Most commercial deposits are composed of fragments in the lapilli size range. In the United States, pumice fragments having one dimension of 5 cm or more are legally defined as block pumice. The procedures for acquiring pumice from federal land are determined in part by this definition and are described in a later section.

(A) Large vesicle cavity in the Mount Mazama (Crater Lake) climactic pumice, Oregon.

(B) Coarsely vesicular pumice from Mono Craters, California, marketed as Featherrock.

(C) Bend pumice, Bend, Oregon, used for lightweight aggregate.

(D) Highly elongated vesicles from air-fall deposit near Burns, Oregon. Individual strands are tubular vesicles.

(E) Finely vesicular pumice from Hess Pumice Products pit near Malad City, Idaho. Even small particles are vesicular and friable, making the material suitable for fine abrasives and polishes.

Origin

The science of volcanology has grown rapidly, particularly in the last 50 years. Both field and laboratory studies have greatly expanded the understanding of eruptive rocks and eruptive processes. Cas and Wright (1988) and their extensive list of references detail much of this work.

The formation and preservation of highly vesicular rocks involve the interplay of a large number of variables, including

temperature, viscosity, gas pressure, and diffusion rates within the erupting magma and external conditions such as wall rock permeability, water influx, vent blockage, wind conditions, and whether the eruption is subaerial or subaqueous. None of these is constant and may change significantly, even during a single eruptive event.

Basaltic magmas tend to be more fluid than more silicic magma and, as they near the surface, degas quickly without generating a stable vesicular structure. Even after vesicle formation, scoria particles may be fluid enough to collapse on impact or to adhere to each other, forming a dense mass rather than a friable, porous deposit.

Silicic magmas are less fluid and offer less opportunity for gas escape and the collapse of vesicle walls. Conditions that reduce gas escape—such as high magma viscosity, impermeable wall rock, or a blocked vent—may lead to eruptions explosive enough to shatter the vesicle walls, generating a fine ash rather than a vesicular particle. Pumice particles entrained in a pyroclastic flow may be reheated enough to soften and collapse into nonvesicular glass.

The unconsolidated nature and low density of pumice and scoria deposits make them readily susceptible to erosion, and the extremely large surface area of the irregular vesicular particles promotes rapid chemical weathering. As a result, most deposits of pumice and scoria are geologically young, rarely more than a few million years old and often only a few thousand years old.

Types of Pumice Deposits

Pumice deposits can be broadly classified into four major types: flows and domes, air-fall deposits, pyroclastic flows, and epiclastic (reworked) deposits. There are gradations between types and deposits and there may be a mixture of types reflecting variations in eruption conditions. Changes in wind direction, blocking and clearing of the vent, increase in vent diameter, influx of water into the magma chamber, influx of a different magma, and rapid gas exsolution by unloading and depressurization may contribute to the character of the resulting ash and pumice deposits.

Flows and Domes
